Abstract

This paper shows that immigration positively affected the emergence of organized labor in the United States. I digitize archival data to construct the first county-level dataset on historical U.S. union membership and use a shift-share instrument to isolate a plausibly exogenous shock to the labor supply induced by immigration, between 1900 and 1920. Counties that received more immigration experienced an increase in the probability of having any labor union, the number of union branches, the share of unionized workers, and the number of union members per branch. The increase occurred more prominently among skilled workers, especially in counties more exposed to the immigrants' labor competition, and in areas harboring less favorable attitudes towards immigration. Taken together, these results are consistent with existing workers forming and joining labor unions for economic as well as social motivations. The findings shed light on a novel driver of unionization in the early 20th-century United States: in the absence of immigration, the average share of unionized workers in this period would have been 23% lower. They also identify an unexplored consequence of immigration: the development of institutions that aim to protect workers' status in the labor market, with lasting effects into the present.

First version: August 2023. I am indebted to Joel Mokyr, Matthew Notowidigdo, Nancy Qian, Marco Tabellini, and Edoardo Teso for extensive advice and guidance throughout this project. I thank Devis Decet, Henry Downes, Georgy Egorov, Silvia Farina, Price Fishback, Carola Frydman, Walker Hanlon, Leander Heldring, Joris Mueller, Laura C. Murphy, Santiago Pérez, Nicola Persico, Massimo Pulejo, Hazal Sezer, Miguel Talamas, Silvia Vannutelli, seminar participants at CREI, Northwestern, Nottingham, Tilburg, UPF, and USC, and conference participants at the EHA (Pittsburgh 2023 and Sacramento 2024) and ASSA (San Antonio 2024) Annual Meetings, 2024 NBER Summer Institute (DAE), 2024 NICEP conference, and 2024 Junior Economists Meeting for helpful comments and conversations; Kellogg Research Support for help in obtaining and digitizing historical data; and Xueyan Li for excellent research assistance.

1 Introduction

Labor unions have long been a central institution in labor markets across advanced economies. Throughout the 20th century, they played a significant role in reducing inequality (Farber et al., 2021), improving working conditions (Rosenfeld, 2019), and shaping policy through active political engagement (Ahlquist, 2017). Despite fluctuations in membership, unions remain integral to today's economy.¹ Given their sustained importance, however, it is striking how little evidence exists on the factors driving their emergence and growth. This paper aims to fill this gap with systematic empirical evidence.

The origins of modern organized labor can be traced back to the Industrial Revolution. One prevailing theory for the rise of unions during this period centers on the increased capital intensity in industrial production, which shifted bargaining power from laborers to the owners of capital (Foner, 1947). A related hypothesis suggests that workers organized in response to growing labor competition (Taft, 1964), which intensified during this period as boosts to agricultural productivity relieved labor from farming, and both total population and the urban population share grew.

This paper investigates the second mechanism: the effect of a large and protracted increase in the labor supply on the formation and expansion of labor unions, leveraging the episodes of mass immigration to the United States of the early 20th century. The effect is *ex ante* ambiguous because it influences both workers' incentives to organize and capital owners' ability to undermine organized labor. On the one hand, the increased competition for jobs can motivate workers to unionize in response to the economic threats to their employment and wages. On the other hand, a larger labor supply lowers the cost to business owners to replace uncooperative workers and break strikes. Thus, how an increased labor supply impacts unionization is ultimately an empirical question.

The context of the early 20th-century United States provides an ideal setting to answer this question. First, the U.S. economy was already the largest in the world (Bolt and Van Zanden, 2020) and the labor movement experienced its first national expansion at the turn of the century (Foner, 1947). Second, these years witnessed the creation and growth of several labor unions that remain influential today (Stewart, 1926), despite the legal and judicial frameworks of the time allowing employers to easily dismiss and replace unionizing workers (Taft, 1964). Third, this context provides a natural experiment to establish causal identification, given by the large and prolonged influx of European immigrants during this period, often referred to as the Age of Mass Migration (Hatton and Williamson, 1998).

¹In the U.S., they recently gained historic victories for several categories of workers, including autoworkers, UPS drivers, and Hollywood writers (Ewing and Boudette, 2023; Hadero and Ott, 2023). In Europe and Canada, where collective bargaining also boasts a long tradition, organized labor continues to expand to previously unorganized sectors, shape the policy agenda, and improve labor market conditions (OECD, 2019).

This study addresses two key challenges in examining the relationship between immigration and unionization. The first is the need for disaggregated data on the presence and membership of labor unions. The only available historical data measure unionization at the state or national level and, therefore, do not allow for analyses across local labor markets. The second challenge is establishing causal effects. For example, the presence of unions may deter immigration. Such reverse causality would result in a negative association between immigrant flows and union presence. Alternatively, both the size of unions and immigration may increase in response to economic growth. Such joint determination would lead to a positive association between unionization and immigrants.

To measure unionization, I hand-collect and digitize archival documents on the location, quantity, and membership of labor union branches across the United States. The main sources of these records are the convention proceedings of the state federations of labor, which report detailed information on the number and location of union branches within each state's territory, along with the names of the delegates sent by each branch to the conventions. I collect these data every 10 years between 1900 and 1920. To calculate the membership of each local branch, which was never systematically recorded in any historical document, I exploit the different constitutional rules of these state organizations, which specified that local union representation at the conventions be proportional to their membership. I complement these data with proceedings of national unions' annual conventions to improve and validate these measures. The information is then aggregated to the county and year levels, and merged with the historical U.S. Census. These data constitute the first comprehensive dataset measuring historical union presence and density (the share of unionized workers) at the county level in the United States.

To estimate the causal effect of immigration, I use a shift-share instrumental variable ([Card, 2001b](#)) to exploit plausibly exogenous variation in the flow of immigrants across counties in each decade. The instrument interacts the 1890 share of immigrants living in a given U.S. county and born in different European countries with the aggregate immigration flows from each country to the United States between 1890 and 1920. This identification strategy is motivated by the empirical regularity that immigrants tend to settle where other migrants from their own country of origin had previously settled, a process known as *chain migration*. The key underlying assumption is that, conditional on controls, the unobserved factors that affected unionization outcomes must not be jointly correlated with the 1890 composition of Europeans' enclaves across U.S. counties and the out-migration patterns from European countries after 1890.² I estimate 2SLS regressions that include county and year fixed effects, in addition to baseline county characteristics which are correlated with the initial presence of immigrants, such as the share of population in farming and in manufacturing, the number of coal mines per inhabitants, and an

²For a formal discussion of the validity of shift-share designs, see also [Adao et al. \(2019\)](#), [Borusyak et al. \(2022\)](#), [Goldschmidt-Pinkham et al. \(2020\)](#), and [Jaeger et al. \(2018\)](#).

indicator for the presence of a railroad in the county, interacted with year dummies.

The main results of this paper show that immigration positively affected the emergence of organized labor. Counties that received more immigrants as a fraction of the population experienced an increase in the probability of having at least a branch of a labor union, the number of union branches, the share of unionized workers, and the number of union members per branch. This finding documents empirically a novel driver of unionization and highlights an unexplored effect of immigration in the labor market. According to the 2SLS estimates, a four percentage point (one standard deviation) increase in immigration raised the share of the unionized workforce by over one percentage point, or roughly 35% of the sample mean. Immigration positively impacted unionization along both the extensive and the intensive margin, as new counties saw the establishment of labor unions and those with an existing labor movement experienced an expansion in its size. A back-of-the-envelope calculation reveals that in the absence of immigration, the average union density (i.e., the share of unionized workers) between 1900 and 1920 would have been 23% lower. The estimates are robust to a variety of sensitivity checks, such as using an alternative instrument that replaces actual immigration flows with plausibly exogenous ones and combining the instrument with a matching strategy.³ The findings are also not sensitive to the inclusion of several additional controls, such as the initial size of the immigrant population, the baseline shares of the labor force in major industries and occupations, and measures of income and economic growth.

In the second part of the paper, I examine the mechanisms behind the expansion of organized labor. First, I explore whether existing workers created or joined labor unions as a response to the economic challenges posed by immigration. Given the political and legal framework of this period, when the law did not grant workers the right to organize and employers frequently resorted to strikebreakers to suppress unionization efforts (Foner, 1947; Taft, 1964), such a response should be more likely to succeed in occupations with entry barriers. While immigrants were perceived as a threat to employment and wages across all occupations (Asher, 1982; Mink, 1986; Olzak, 1989), they could not immediately replace incumbent workers in these jobs. This dynamic should put existing workers in a stronger position to unionize and limit the future entry of immigrants into their roles. Differences in skill requirements across occupations provide a testing ground for this mechanism. Supporting this hypothesis, immigration strengthened labor unions in skilled trades, such as craft workers, while having no statistically significant effect on the unionization of low-skilled workers, such as operatives and laborers.

³Although previous work has argued that this period is particularly suited to the use of shift-share instruments (Abramitzky et al., 2023; Tabellini, 2020), the alternative instrument, which relies on predicted flows using weather shocks across European countries (Sequeira et al., 2020), allows me to identify causal effects from the exogenous variation in the shocks, while allowing the exposure shares to be endogenous (Borusyak et al., 2022). Moreover, I build on Bazzi et al. (2023) and combine the instrument with a matching exercise, which selects within-state county pairs with the closest levels of union presence in 1890. All the robustness checks are described in Section 5.3.

Second, I investigate whether counties where immigrants directly competed with existing workers experienced a larger increase in unionization. To determine exposure to immigrant labor market competition, I measure whether the occupations prevalent among immigrants entering the United States in each decade were also predominant among U.S.-born workers in a given county at the start of that decade. Consistent with the hypothesis that unionization was a response to economic concerns raised by immigration, skilled workers were more likely to unionize in counties with higher exposure to labor competition from immigrants. In contrast, competition from immigrants slowed union growth among low-skilled workers, whose bargaining power was undermined by the increased availability of replacement labor.

Third, I explore whether social motivations also contributed to the observed development of labor unions. Given the nativist rhetoric that accompanied the labor movement's support for immigration restrictions throughout the first half of the 20th century (Goldin, 1994; Mink, 1986), one may expect that the cultural dissimilarity of immigrants could provide a further incentive for workers to organize and exclude the newcomers from the labor market. I find evidence consistent with this hypothesis. I show that the increased unionization was more prominent following an inflow of immigrants from Southern and Eastern Europe, whom part of the labor movement considered "slavish, ignorant and unassimilable," and therefore, a threat to American society (Collomp, 1988; Mink, 1986). Further, I show that unionization grew more in places harboring less favorable attitudes towards immigration. In the absence of a direct measure, I use two proxies that likely reflect a county's higher hostility towards immigrants. The first is the historical vote share for the Know Nothing Party, a nativist political party that, in the mid-1850s, ran on an anti-Catholic and anti-Irish platform (Alsan et al., 2020). The second is the baseline level of residential segregation between U.S.-born individuals and European immigrants. Since residential segregation usually arises either from collective action to exclude minorities or from individuals from the majority group moving away from ethnically mixed neighborhoods (Boustan, 2010, 2013), this characteristic likely reflects higher levels of discrimination against immigrants. Using either of these proxies, I find that immigration strengthened organized labor more prominently in counties with higher resentment towards immigrants.

Next, I rule out several alternative channels that could drive the results. First, I show that the findings are unlikely to be explained by immigrants disproportionately participating in unions. Given that information on the country of origin of individual union members does not exist, I provide suggestive evidence against this alternative explanation by examining the relationship between immigration and the origin and ancestry of local union leaders, inferred from their last names. I document that the share of union leaders with last names common among U.S.-born individuals (or those of North-Western European ancestry) increased overall during this period. At the same time, immigration

did not lead to a rise in the proportion of immigrant last names among local union leaders. Moreover, I exploit variation in the strength of labor unions and socialist parties across Europe at the beginning of the 20th century and document that the inflow of workers from countries with active labor movements or stronger support for socialism did not contribute to the increase in unionization. Second, I show that counties with higher levels of immigration did not experience different economic growth, as there was no effect on labor force participation, manufacturing output, or the share of workers in skilled occupations. This indicates that economic expansion or increased demand for skilled labor is unlikely to explain the observed patterns in union growth.

In the last part of the paper, I explore the economic implications of this immigration-induced unionization. Although not all these findings should be interpreted as causal, they still provide key insights into short- and medium-run trends associated with a higher presence of organized labor. First, I investigate whether incumbent workers turned to occupations that had union representation in their county, to protect themselves against the economic challenges brought by immigration. I find that immigration increased the share of U.S.-born workers in unionized skilled trades, and, at the same time, reduced their concentration in skilled occupations without local union representation. This finding suggests that U.S.-born workers may have turned to occupations where organized labor could shield them from the potential adverse consequences of immigration. Second, I investigate whether the effects of early 20th-century immigration on unionization, documented for the first time in this paper, persist into the present. To align with the current unionization measures from [Macpherson and Hirsch \(2023\)](#), I aggregate the data at the metropolitan-area level and employ the same shift-share instrument described earlier to assess the impact of historical immigration on present-day private sector union density. Notably, metropolitan areas that experienced larger waves of immigration continue to show higher private sector union density today. Consistent with the union growth patterns of the early 20th century, which were largely concentrated in the construction sector, these effects are also concentrated in the construction sector. This suggests that the conditions that facilitated the initial rise of labor unions in the early 1900s provided a lasting advantage to the labor movement which has persisted over time. Third, I explore a central economic question related to labor unions: their role in reducing inequality ([Card, 2001a](#); [DiNardo et al., 1996](#)). I construct three measures of wage inequality using U.S. Census data from 1940, the first year data on wages were collected. I then investigate their cross-sectional correlation with unionization in 1920, controlling for state fixed effects and the controls in the baseline specification. The results indicate that higher unionization levels are associated with lower wage inequality.

In summary, the empirical findings of this paper show that immigration substantially contributed to the emergence and expansion of organized labor in the early 20th-century United States. Moreover, the results are consistent with existing workers forming and

joining labor unions for economic as well as social motivations.

Related literature. The findings of this paper contribute to several broad literatures. First, they speak to the studies on organized labor, and labor unions more specifically. While a rapidly growing recent empirical literature has studied labor unions and analyzed their impact on a wide range of economic and political outcomes, both in historical and contemporary settings (Ahlquist, 2017; Ash et al., 2019; Barth et al., 2020; Biasi and Sarsons, 2022; Bittarello, 2018; Card, 2001a; Collins and Niemesh, 2019; DiNardo and Lee, 2004; Farber et al., 2021; Feigenbaum et al., 2018; Naidu, 2022; Naidu and Reich, 2018; Rosenfeld and Kleykamp, 2012; Rosenfeld, 2019; Sojourner et al., 2015; Schmick, 2018; Wang and Young, 2022), this study is the first to study the determinants of their early development with systematic empirical evidence. The results identify immigration as a key factor that led to the emergence and growth of modern unions during a highly formative period for the American labor movement.

This paper also relates to studies that explore the historical drivers of unionization (Alesina and Glaeser, 2004; Archer, 2010; Asher, 1982; Bernstein, 1954; Briggs, 2001; Burgoon et al., 2010; Brody, 1993; Collomp, 1988; Foner, 1947; Freeman and Medoff, 1984; Griffin et al., 1986; Hannan and Freeman, 1987; Haydu, 1988; Karadja and Prawitz, 2019; Lipset and Marks, 2000; Montgomery, 1979; Moody, 2019; Naidu and Yuchtman, 2016; Olson, 1965; Sezer, 2023; Sombart, 1976; Taft, 1964; Willoughby, 1905; Webb and Webb, 1894; Wolman, 1924), and those that analyze the causes of its decline in recent decades (Acemoglu et al., 2001; Ahlquist and Downey, 2020; Clawson and Clawson, 1999; Farber and Western, 2001; Hirsch, 2008; Scruggs and Lange, 2002; Slaughter, 2007; Southworth and Stepan-Norris, 2009; Wallerstein and Western, 2000). This study advances this literature by identifying an unexplored driver of unionization and shedding light on the channels through which it operates.

The data collection effort of this paper also delivers the first comprehensive county-level dataset on historical union presence and membership in the United States, covering almost the entire country. Although a few existing papers have collected historical information on labor unions, those data are either on extinct organizations whose relevance was limited to the 1880s (Garlock, 2009), only cover a limited set of unions and do not contain information on membership (Schmick, 2018), are not disaggregated below the state level (Farber et al., 2021), or measure unionization only in a handful of states (Downes, 2023). The data introduced in this paper, aggregated at the county level for the analysis, but collected at the city or town level, make a significant advancement in studying geographic patterns of early unionization, and open avenues for future research on the medium- and long-term consequences of organized labor in the United States.

This paper also speaks to the vast literature on immigration. The results are related to the strand of this literature that examines its effects on labor market outcomes (see Abramitzky and Boustan, 2017 and Peri, 2016 for a review). This paper is the first to doc-

ument that historical immigration positively affected the emergence and development of one of the most relevant labor market institutions, with heterogeneity in unions' presence and strength that persists until today.

Further, this study relates to the vast literature about the consequences of immigration on domestic workers' employment and wages, which has not reached an agreement on whether immigration has a positive, negative, or null effect (Dustmann et al., 2016). In particular, the findings of this paper are in line with Abramitzky et al. (2023), Card (2001b, 2005, 2009), Foged and Peri (2016), Ottaviano and Peri (2012), and Tabellini (2020), who find negligible or positive impacts on domestic workers. The results of this study suggest that labor unions may play a role in mediating the possible adverse effects of immigration on domestic workers' wages and employment.

Finally, this paper is closely related to the recent political economy studies showing that higher levels of immigration increased the vote share for conservative politicians and support for anti-immigration legislation, both historically and recently (see Alesina and Tabellini, 2024 for a review). The results of this study identify a novel and unexamined consequence of immigration on the development of institutions that have had – and still have today – vast political influence. Although anecdotal and historical evidence has acknowledged the instrumental role that organized labor played in the introduction of immigration restrictions in the 1920s (Goldin, 1994; Mink, 1986), this paper is the first to empirically estimate a causal and positive effect of immigration on unionization, and document that this was due to both economic and social motivations. Moreover, this paper is related to the work by Alesina and Glaeser (2004), which links the weak labor and socialist movements of the United States to its ethnic diversity. The results of this study shed further light on this phenomenon, showing that reactions to immigration can foster unionization, partly offsetting other opposing forces that may slow down its growth.

Outline. The remainder of the paper is organized as follows. Section 2 describes the historical background. Section 3 presents the data. Section 4 introduces the empirical strategy and the instrument for immigration. Section 5 presents the main results and a summary of the robustness checks. Section 6 sheds light on the mechanisms that are driving the effect. Section 7 discusses the economic implications of the findings and the long-term effects of immigration on unionization. Section 8 concludes.

2 Historical Background

2.1 Labor Unions at the Turn of the 20th Century

A new phase for the American labor movement started around the end of the 1880s, as the American Federation of Labor (AFL) became the largest and most influential group of

labor unions.⁴ By 1890, the main labor organizations that had gained importance during the second half of the 19th century – the Knights of Labor and the independent railroad workers' movements – had practically disappeared,⁵ leaving the field open to new trade unions (Wolman, 1924). These years saw the creation of many new organizations, which later became some of the largest national trade unions still active today.⁶ Between 1880 and 1920, the total number of union members went from 149,000 to over 4.5 million (Figure 1).

The AFL was created as a federation of national unions and organized on the model of craft unionism. This meant that workers were organized based on their particular occupation (or craft).⁷ It adopted the policy of *one craft—one union*, according to which each occupation should have only one union representing it. During this period, the unions in the building construction industry became the most stable and largest organizations.⁸ This industry was dominated by skilled craftsmen, and characterized by small employing units (Taft, 1964). Only a few unions organized unskilled laborers in industrial settings. The United Mine Workers of America (UMWA) was the largest of these, along with unions representing dockworkers and workers in the meat-packing and textile industries. These sectors, mining in particular, were dominated by large employers who owned and operated several plants or mining sites (Beik, 1996) and strongly opposed unionization efforts (Northrup, 1943).

The AFL-affiliated national unions were organized into branches, called *locals*. The branches were responsible for bargaining agreements directly with individual employers (based on guidelines decided by the national union) to regulate wages, work hours, and conditions of employment. Unions also maintained funds to pay workers' benefits (in the event of strikes, injury, disability, or death), and regulated the terms of apprenticeship within the craft (Stewart, 1926). In most cases, the collective agreements specified that only union members could be employed (*closed-shop* clause). Both mandatory membership and apprenticeships gave unions effective control over which workers could enter the skilled occupations they organized.

Until the mid-1930s, there was no federal law requiring employers to recognize unions

⁴The American Federation of Labor was founded in Columbus, Ohio, on December 8, 1886, and rapidly became the main federation of unions in the country (Foner, 1947).

⁵Scholars have attributed the abrupt decline of these labor unions to a variety of factors, including their lack of a stable and permanent organizational structure, and their overly ambitious political agenda (Taft, 1964; Wolman, 1924).

⁶The International Brotherhood of Teamsters, the International Brotherhood of Electrical Workers, the International Association of Machinists, and the United Brotherhood of Carpenters – even now among the 10 largest private sector unions – were established between 1881 and 1903. Moreover, the AFL (now merged with the more recently created CIO) is still the largest federation of labor unions, representing more than 12 million workers (U.S. Department of Labor, 2022).

⁷The main alternative model is *industrial* unionism, in which all workers in the same industry are organized by the same union, regardless of their skill level.

⁸The bricklayers and the carpenters' unions were the dominant organizations among building trades.

or punishing their retaliatory behavior against union members. This situation promoted an environment where company owners, with the support of the courts, made use of strikebreakers, lockouts, retaliatory firing, and other strategies to oppose unions and prevent their organization (Foner, 1947; Taft, 1964).⁹

2.2 The Age of Mass Migration

Between 1850 and 1920, around 30 million Europeans moved to the United States (Hatton and Williamson, 1998), raising the share of the foreign born population to over 14% (Figure 2 and Figure 3). The mix of origin countries changed substantially over time. Until 1890, most immigrants were from the United Kingdom, Ireland, Germany, and Scandinavia. Thereafter, as transportation costs decreased (Keeling, 1999), the bulk of immigrants came from the rest of Europe. In 1850, immigrants from Northern or Western Europe were 92% of the foreign-born population, while less than 1% had arrived from Southern, Central, or Eastern Europe. By 1920, these shares were 40% and 43%, respectively (Figure 4). Europeans from the new origin regions were different from those who had arrived in the previous decades: they were significantly less skilled, spoke unfamiliar languages, and were not Protestant (Hatton and Williamson, 1998, 2006).

The waves of mass immigration increased enormously the supply of labor, which had already been expanded by the shift of population from rural areas to cities in the 1880s. Often the newly arrived immigrants, eager to earn a livelihood in a new country, made their first appearance into the American workforce as strikebreakers, hired by business owners in order to undermine the incumbent workers' bargaining power and unionization efforts (Foner, 1947). Over the years, the political climate grew hostile towards European immigrants, based on concerns about labor market competition and xenophobia toward new arrivals (Goldin, 1994). In response, starting in the late 1890s, members of Congress proposed legislation to limit immigration, and in 1917, Congress eventually introduced a literacy requirement for all immigrants.¹⁰ Though immigration temporarily slowed down during World War I, after the end of the war it immediately rose again, resurrecting earlier anti-immigration fears. Consequently, in 1921 Congress passed the Emergency Quota Act and introduced a temporary limit to immigration. In 1924, the National Origins Act made this restriction permanent and more stringent (Abramitzky and Boustan, 2017). The immigration quotas remained in effect for the next 40 years, until

⁹Federal legislation of 1898 (Erdman Act) guaranteed the right to unionize only to railroad workers. Several states passed laws in the 1890s prohibiting employers from discharging employees for belonging to a union. However, whenever the labor movement succeeded in obtaining legislation in its favor, courts weakened or entirely wiped out such statutes by declaring the laws unconstitutional (Foner, 1947; Taft, 1964).

¹⁰One of the first attempts to limit immigration was the legislation introduced by Henry Cabot Lodge, the Republican senator from Massachusetts, which required a literacy test for all potential immigrants. President Cleveland then vetoed the bill.

they were eliminated in 1965 by the Immigration and Nationality Act.

2.3 The Labor Movement and Immigration

Organized labor has always been concerned about the potential negative consequences of labor supply expansions, particularly those caused by immigration (Taft, 1964). This is the main reason why it favored immigration restrictions since its inception. In 1881, in the founding meeting of its precursor organization, the AFL adopted a resolution against Chinese laborers and lobbied Congress to ban Chinese immigration through the Chinese Exclusion Act of 1882 (Foner, 1947). In 1885, the labor movement succeeded again when the Alien Contract Labor Law (also known as the Foran Act), which banned the importation of foreigners to perform labor in the United States, was approved.¹¹ In 1896, in response to the shift of immigration to ethnic and national groups whose schooling levels, skills, and standards of living were substantially below those of previous groups, the AFL endorsed further restrictive measures. It was widely held that Southern and Eastern Europeans lowered wages, dragged down working conditions, were not responsive to the discipline of labor unions, and therefore constituted a threat to the American working man (Mink, 1986; Taft, 1964). The federation vigorously supported further restrictive measures until it obtained the introduction of the 1921 and 1924 nationality quotas (Goldin, 1994).

Throughout this period, the labor movement used increasingly popular racial and eugenics-based arguments to discuss threats to employment and gain momentum in calling for an outright ban on European immigration.¹² Nativism was triggered by the increased presence of foreign laborers, which inundated labor markets, and was intensified by the mounting pressure of mechanization (Mink, 1986; Yellowitz, 1981). These events added credibility to the fears that machines and the new unskilled workers could substitute skilled unionized labor (Olzak, 1989), and led unions to concentrate on securing job control for skilled workers by organizing the workplace and the work process (Mink, 1986). At the same time, the immigration-induced expansion of the labor supply was

¹¹ Representative Foran, the sponsor of the bill, decried the "large numbers of degraded, ignorant, brutal Italians and Hungarian laborers" for imperiling the racial heights of the republic: "They know nothing of our institutions, our customs, or of the habits and characteristics of our people. [...] They are brought here precisely in the same manner that the Chinese were brought here [...] Being low in the scale of intelligence, they are [...] willing slaves. [...] The fact that American workingmen are vastly superior to these aliens in intelligence, skill, moral and social culture will no doubt be admitted" (Mink, 1986).

¹² Statements made by union men expressing hatred for new immigrants abound. In 1884, a labor leader described Hungarian laborers as a menace because "they work for little or nothing, live on a fare which a Chinaman would not touch, and will submit to any and every indignity which may be imposed on them." Railroad workers in Kankakee, Illinois, objected to: "Italians [...] unloaded in cities from cattle cars; they sleep in huts; they eat stale bread [...] the worst kind of meat and a small amount of rice. [...]. Send them away or we will kill them as one kills mad dogs." American laborers complained that most immigrants were "only scavengers to our country" and that men who could not speak "our language" often beat out natives for jobs." (Asher, 1982).

deemed responsible for weakening unions' bargaining power, by creating a reservoir of potential strikebreakers and freeing employers from the constraints of a tight, unionizing labor market ([Montgomery, 1979](#)).

3 Data

This study relies on a novel micro-database that combines labor unions' records with labor market outcomes, between 1900 and 1920.

In this section, I describe the data collection effort, the main sources of the data, and present summary statistics.

3.1 Dataset on Union Presence and Membership

I assemble the first panel dataset on unionization for the period 1900–1920. This also constitutes the first comprehensive dataset on historical union density measured at the county level in the United States. Most existing studies on modern labor unions in a historical period rely on aggregate national estimates, since microdata on union status were first collected by the Current Population Survey (CPS) only in 1973. There are a few notable exceptions. [Schmick \(2018\)](#) collects data on the presence of local branches of some national unions in the years 1882, 1892, and 1902. However, the dataset contains no information on membership and covers a different set of unions in different years in a time period that precedes the first significant expansion of the labor movement and the largest waves of immigration. [Farber et al. \(2021\)](#) combine survey data, primarily from Gallup, to compute historical levels of union membership for most of the 20th century. However, their data are not disaggregated below the state level, and only start in 1937, after immigration restrictions had been in place for over a decade and the first national expansion of the American labor movement had occurred. Similarly, [Downes \(2023\)](#) constructs county-level union membership estimates for selected years in the mid-20th century. However, his data start in 1920 and are limited to five states, hence also unsuitable to study the questions of this paper.

The dataset I assemble to conduct the empirical analysis combines newly digitized historical records on labor unions from several sources.

Convention proceedings of the state federations of labor. The main sources of the dataset on unionization are convention proceedings of the state federations of labor, which were state-level subordinate bodies of the AFL. Their functions were mainly legislative and propagandist, and they were composed of representatives from all the local branches of the AFL-affiliated national unions within the state ([Stewart, 1926](#)). Local branches (also called local unions, or locals) were a lower level of organization of national unions, and represented workers in either a single employment unit or from several work

sites. By 1920, members of AFL unions constituted more than 80% of the total private-sector union membership (Wolman, 1924). Each state federation of labor met annually in conventions to enact legislation and elect general officers. All affiliated local unions were entitled to representation.¹³

I digitize the proceedings of these conventions every 10 years between 1900 and 1920.¹⁴ From these documents, I extract the lists of union branches (*locals*) represented at the conventions, along with the union name and branch number, their location, the number of delegates representing them, and the names of such delegates (Figure A.1). Each federation had specific rules to define the number of delegates that could represent a local branch, which often varied over time. Importantly, they established that locals should be represented proportionally to their membership (Figure A.2).¹⁵ I therefore combine the information on the delegates from the convention proceedings with the details on the representation rules contained in the constitutions of each state federation of labor. Using this information, I construct an estimate of union membership for each local branch. Since the representation rules were often expressed in terms of ranges (e.g., one delegate every 100 members), I use the mid-points of these intervals as the estimates of membership. For example, if the constitution states that a branch is represented by one delegate every 100 members, its membership is estimated to be 50 if one delegate is present at the convention, 150 if two delegates are recorded, and so on. The results are unchanged if membership is estimated using the lower or the upper bound of the intervals instead.¹⁶

I geocode the location of all the union branches based on their town, village, or city, and retrieve their coordinates. I use the names of each branch's national union to establish which occupations and industries they operated in.¹⁷ Finally, I aggregate the membership of the union branches at the county level to obtain a measure of union membership, both total and by occupation.

Proceedings of the national conventions of AFL unions. I complement the data from the state federations of labor with analogous information collected directly by the AFL-affiliated national unions. Similar to the state federations, the AFL-affiliated unions met in

¹³The only exceptions were recently established branches, those that had payments in arrears in the months before the convention (usually three months before), and branches expelled or suspended by their national organization.

¹⁴In case the proceedings for any of these years were not available, or did not contain the information needed (e.g., location of the union branches), I digitize the analogous document for the convention that took place either the following year or two years later. If those documents are also not suitable or unavailable, I digitize the one of the convention from the previous year or two years before.

¹⁵The following state federations of labor never adopted a proportional representation in the period 1900–1920: Kansas, Kentucky, Louisiana, Maryland, North Dakota, New Mexico, and Tennessee. For this reason, these states do not enter the sample.

¹⁶These results are not shown for brevity, but are available upon request.

¹⁷As described in Section 2, each AFL national union organized workers in a specific occupation. Their names always indicated the occupations or industries they represented (e.g., United Brotherhood of Carpenters and Joiners, Brotherhood of Painters and Decorators, International Association of Machinists, United Mine Workers of America, etc.).

national conventions to legislate, elect officers, and set guidelines for the local branches to follow in their bargaining agreements. I digitize the proceedings of these conventions for six of the largest AFL-affiliated unions of this period, every 10 years between 1900 and 1920.¹⁸ The members of these six unions accounted for approximately 40% of the over 100 AFL-affiliated unions' total membership between 1900 and 1920 (Wolman, 1924).¹⁹ I follow a procedure analogous to the one described for the proceedings of the state federations of labor, and collect data on the lists of local branches, their location, and the names and number of delegates representing them. Next, I construct an estimate of the membership of each of these locals, following the representation rule listed in the convention proceedings or in the constitution of each of these organizations. Finally, I aggregate the data at the county level.

These data sources complement the records from state federations in three main ways. First, they validate the estimates constructed using the main data source. In particular, for the six unions that I observe across both sources, I am able to compare the estimates of union membership and the number of branches. In all cases, the measures display a highly positive correlation (Figure A.3). Nonetheless, some branches may appear in only one of the two types of convention documents I digitize. This may occur because one branch was established too recently before a convention and did not yet qualify to send delegates according to organization-specific rules. Similarly, it could have been formed between the state federation and the national union convention; hence, it could only be observed in one of the two documents. Another possibility is that some delegates may have been erroneously omitted from the roll calls of the meetings.²⁰ Any of these occurrences would lead to an underestimate of the number of members and/or the number of branches in a given county if only one of the sources was used. Unfortunately, there is no way of knowing with certainty if and how many locals fall into these circumstances, since this information is never systematically reported. However, by combining information from different sources (and collected by different entities), I am able to reduce these instances of mismeasurement. This constitutes the second main contribution of this data source. Third, these additional archival records allow me to expand the time and geographical coverage of the dataset, because some state federations of labor were con-

¹⁸As above, if suitable documents are not available for 1900, 1910, or 1920, I digitize the analogous documents for the convention that took place in one of these alternative years (in order of preference): one year later, two years later, one year before, or two years before.

¹⁹These unions are: the Bricklayers, Masons, and Plasterers International Union of America (BMPIU); the International Association of Machinists (IAM); the International Brotherhood of Teamsters (IBT); the International Typographical Union (ITU); the United Brotherhood of Carpenters and Joiners (UBC); and the United Mine Workers of America (UMWA). These are all the unions, among the 10 largest, that systematically and consistently reported information in their convention proceedings about delegates and the local branches they represented, and whose proceedings are still available either in physical or digital copy.

²⁰Additionally, some locals may have had payments in arrears to either the state federation or the national organization, and therefore did not qualify to send delegates to one of the two conventions.

stituted (and hence convened for the first time) only after 1900.²¹ Relying only on the first data source would lead to measure no presence of union branches and zero union membership for counties in states and decades before the first federation of labor's convention. Although the lack of an AFL state subordinate body intrinsically suggests a limited presence of organized labor, it is still possible that some of the largest national unions may have already been present in at least some counties of these states. The additional information on the branches (and its delegates) of these six large unions operating throughout the whole U.S. territory in 1900, 1910, and 1920, allows to more accurately measure unionization at the early stages of a state's labor movement.

Combined data sources. To construct the final measures of unionization, I combine the information collected from the two sources described above.²² I first reduce the number of missing observations and misreportings from each of these sources by linearly interpolating the number of union branches and members for counties that are not reported in the convention proceedings of a certain year, but that have representation both in the previous and following decade.²³ Next, for the six unions observed across both types of documents, I compute the number of members and branches in each county and year by averaging the ones from each source. When only one data source reports a positive membership or number of local branches, I use that value in the analysis. Finally, I sum the total number of branches and members across all unions at the county-decade level, and obtain the total number of these quantities in each county over time.

In order to construct a measure of union density, I divide the number of union members by the size of the nonfarm labor force as measured in the U.S. Census.²⁴ Addition-

²¹The following state federations of labor first convened after 1900, the first year of the empirical analysis: Alabama (1901), Arkansas (1905), Arizona (1912), California (1906), Delaware (1923), Florida (1901), Idaho (1916), Kansas (1907), Louisiana (1913), Maryland (1905), Mississippi (1918), North Carolina (1907), North Dakota (1912), Nebraska (1909), New Hampshire (1902), North Carolina (1907), North Dakota (1912), Nebraska (1909), New Hampshire (1902), New Mexico (1914), Nevada (1921), Oklahoma (1904), Oregon (1902), Rhode Island (1901), South Carolina (1915), South Dakota (1920), Utah (1904), Vermont (1902), Washington (1902), West Virginia (1903), and Wyoming (1909). Consistently with the rest of the data collection, the proceedings of federations constituted in 1901 or 1902 are attributed to the Census year 1900.

²²In Section 5.3, I show that the results are unchanged when using only the state federations of labor proceedings to measure the number of union members and union branches in a county.

²³Counties may wrongly appear to have no union branches or members in a certain year due to one of the following reasons: error in assigning a locality to the correct county because of homonymous locations, a partial or incorrect reporting of the delegates present at the convention, or county-specific reasons for why no delegate was actually not sent to one of the two conventions. The underlying assumption for this exercise is that a county with union branches and members in, say, 1900 and 1920, will not realistically have zero branches and membership in 1910. I also collect available data for the state federation conventions that took place in 1930 in order to linearly interpolate the data from the first source for the year 1920. Importantly, the results are unchanged if this step is not conducted (see Section 5.3).

²⁴This includes all men ages 16–64 in nonfarm occupations, except for managers, proprietors, and private household service workers, as these groups were typically ineligible to unionize during this period (Stewart, 1926; Wolman, 1924). In case the total number of estimated union members exceeds the labor force, union density is coded to be one. This is a rare event, which occurs for the main measure of union density only in three out of the 2,628 county-year observations of the main sample. In Section 5.3, I also show that

ally, I construct an indicator for whether a county has any union, the number of union branches within its territory, and their average size, defined as the number of members divided by the number of branches. All four variables are then winsorized at the 1% to remove outliers. As a final validation exercise, I compare these measures of union density to those contained in another existing historical dataset. While only aggregated national estimates of union membership exist for the period studied, I ensure that the measures of union density are positively correlated with those calculated at the state level by [Farber et al. \(2021\)](#) using Gallup surveys, starting in 1937 (Figure G.1).

The final dataset contains information on the location and membership of local union branches in over 2,400 counties between 1900 and 1920.²⁵

3.2 Other Data Sources

Immigration and population. The data on county population and on the number of immigrants, by country of origin at the county and national levels, are taken from the decennial U.S. Census of Population. For 1900, 1910, and 1920, I use the full-count Census datasets, made available by IPUMS ([Ruggles et al., 2021](#)). For 1890, I use Census datasets aggregated at the county level, made available by the Inter-University Consortium for Political and Social Research (ICPSR) ([Haines, 2010](#)).²⁶

Labor market outcomes. I compile data on labor force, occupation, and yearly income from the U.S. Census of Population.²⁷

Economic activity. The county-level data on the manufacturing and agricultural sectors come from the Census of Manufacturing ([Haines, 2010](#)) and the Census of Agriculture ([Haines et al., 2018](#)), respectively.

Railroad network. The information on the expansion of the railroad network rely on the database compiled by [Atack \(2016\)](#), based on traced lines from historical map images. The database contains the exact placement of railroad lines over time, between 1826 and 1911.

Coal mines. I digitize the information on the location and number of coal mines from the Report on Mineral Industries of the 1890 U.S. Census ([Day, 1892](#)).

Presidential elections vote shares. The data for the county-level vote shares in presi-

the results are not sensitive to the exclusion of outliers.

²⁵The counties not part of the sample are those in states whose federations of labor did not have a representation rule for branches proportional to their membership (as previously described), whose convention proceeding are not available, or reported only incomplete records (e.g., no information on the location of the branch, or no list of delegates altogether). In Section 5.3, I show that the results are unchanged when extending the analysis to the whole unbalanced sample of counties.

²⁶Since most of the 1890 completed Census forms were lost in a fire, full-count data are unavailable for this Census year.

²⁷Due to the unavailability of the labor force participation status in the 1900 full-count Census dataset ([Ruggles et al., 2021](#)), I proxy for this variable in that year with an indicator for holding any gainful occupation.

dential elections are from Inter-University Consortium for Political and Social Research (ICPSR) (1999).

3.3 Summary Statistics

Figure 5 plots the number of union branches, and Figure 6 union density (the number of union members as a fraction of the labor force), across U.S. counties in 1900, 1910, and 1920. Unionization in 1900 was predominantly concentrated in the Northeast and Midwest. By 1920, unions had also spread to many other regions, including the West and selected areas of the South. Across the country, unionization was more prevalent in urban areas, which also received larger immigration flows during this period. Overall, the maps display substantial variation in the two measures across counties – both within and across states – and over time.

In Table 1, I present summary statistics for the main measures of unionization (Panel A), demographic composition (Panel B), labor force (Panel C), and county characteristics at baseline (Panel D). Throughout the paper, I focus on a balanced panel of 876 urban counties between 1900 and 1920, which account for 70% of the male nonfarm labor force in counties where union data are available, and 55% of the same in the entire country.²⁸

On average, approximately 40% of counties have positive union membership, with just under three union branches per county. In the average county, 4% of the labor force are union members, and each union branch has about 50 members.

The average share of the population living in urban areas is 30%. Immigrants make up 9% of the population, with most originating from Europe. Roughly 2% of the total population consist of European immigrants who have entered the United States within the previous decade.

The average county has approximately 15,000 working-age men (16–64 years old) in the labor force, representing 91% of the male working-age population. Of these, 86% are U.S-born and 12% are European immigrants.

In 1890, a decade before the period analyzed (1900–1920), the average share of European immigrants in the population was 10%. On average, 45% of families worked in farming, and 3% of the population in manufacturing. There were about 1.5 coal mines per 10,000 inhabitants, and 95% of counties were crossed by a railroad.

²⁸This sample restriction reflects the fact that both immigration and unionization were predominantly urban phenomena during this time (Foner, 1947; Taft, 1964). A county is classified as urban if it has a baseline share of urban population greater than zero. Additionally, counties with at least one coal mine at baseline are included in the sample, as the coal miners' union was one of the largest labor organizations (Stewart, 1926), and some mining sites were located outside urban areas. In Section 5.3, I show that the results are robust under alternative sample restrictions, such as using a balanced or unbalanced panel of only urban counties or both urban and rural counties.

4 Empirical Strategy

4.1 Baseline Estimating Equation

To study the effects of immigration on unionization, I focus on the three Census years between 1900 and 1920, and I estimate

$$y_{ct} = \beta Imm_{ct} + \theta_c + \tau_t + X_{ct} + u_{ct} \quad (1)$$

where y_{ct} is the outcome for county c in Census year t , and Imm_{ct} is the number of immigrants as a fraction of the county population. θ_c and τ_t are county and year fixed effects, implying that β is estimated from changes in the fraction of immigrant labor force within the same county over time. X_{ct} are county-level control variables, which are likely correlated with both the pre-1900 settlement of immigrants and the evolution of unionization over time, measured at baseline and interacted with year fixed effects. Throughout the analysis, standard errors are clustered at the county level, and all variables are harmonized to reflect 1930 county boundaries (Hornbeck, 2010).²⁹

In the baseline specification, Imm_{ct} refers to the stock of working-age male European immigrants who entered the United States during the previous decade, as a share of the total working-age (ages 16–64) male population. Focusing on this definition allows for a more confident interpretation of the findings as the consequences of an inflow of new (immigrant) workers into the labor market. All the labor force variables are similarly computed on the sample of working-age men.³⁰

4.2 Instrument for Immigration

Given the hostility of the labor movement towards immigration described in Section 2, we may expect immigrants to settle in counties with less unionization, where the chances of being excluded from certain occupations would be lower. This would cause the ordinary least squares (OLS) estimates of equation (1) to be biased downwards. By contrast, immigrants may prefer counties with a growing labor movement, to the extent that those labor markets might also present more or better job opportunities. This would bias the OLS estimates upwards. In addition, classical measurement error in the immigration data

²⁹Since county boundaries change over time, I maintain consistent geographic units by holding county boundaries constant throughout the sample period. I follow the procedure in Hornbeck (2010) and harmonize all the variables used in the analysis to reflect 1930 county boundaries. This procedure uses area-based weights to harmonize county boundaries across years. Alternative border harmonization procedures that use population-based weights, such as the one in Ferrara et al. (2022), yield almost identical results.

³⁰Over most of the period 1900–1920, union members were almost exclusively men (Wolman, 1924), and female labor force participation was only 25% (92% for men). Results are very similar when considering all immigrants, regardless of their sex, age, or arrival year (Section 5.3).

would attenuate the estimates towards zero.

Baseline instrument. To deal with these endogeneity concerns, I construct a shift-share instrument (Card, 2001b). This approach combines two sources of variation. The first is the *share* of European immigrants from country j living in county c as of 1890 (relative to all immigrants from country j in the United States), which I denote as $\alpha_{c,1890}^j$. The second is the change, or *shift*, in the number of European immigrants from country j entering the United States in a given decade, net of those that eventually settled in county c , denoted by O_{-ct}^j .³¹ Formally, the predicted number of immigrants received by county c between Census year $t - 10$ and t is given by:

$$\tilde{Z}_{ct} = \sum_j \alpha_{c,1890}^j O_{-ct}^j \quad (2)$$

This number is then scaled by county population measured in 1890, $P_{c,1890}$, as the contemporaneous county population would itself be an outcome of immigration.

Underlying this identification strategy is the empirical regularity that migrants tend to settle where other migrants from their own country of origin had settled previously, a process known as *chain migration*. The pre-1890 migration of Europeans is reflected in the term $\alpha_{c,1890}^j$. The choice of 1890 as the base year captures many of the key migration networks established during the early part of the Age of Mass Migration, while also preceding both the peak of immigration flows from Europe and the most significant periods of union growth. (Figure 1 and Figure 2).³² Importantly, 1890 also predates the major shift in the composition of immigration that occurred around the turn of the 20th century (Figure 4). As previous work has argued (Abramitzky et al., 2023; Tabellini, 2020), this period is particularly well-suited for the use of shift-share instruments, not only due to changes in the volume of immigration over time but also because of the variation in immigrants' countries of origin in each decade. Different from Tabellini (2020), who employs an analogous identification strategy to predict immigration between 1910 and 1930, this shift-share instrument leverages additional variation in the composition of immigration that occurred between 1890 and 1900.

Identification assumption. The key identifying assumption behind the instrument described in equation (2) is that, conditional on controls, the unobserved factors that affect unionization outcomes must not be jointly correlated with the 1890 composition of Europeans' enclaves across U.S. counties and immigration patterns from European countries after 1890.³³ Previous work has argued that nation-wide shocks that occurred during the period 1900–1920, and which are exogenous to county-specific characteristics, make this

³¹A similar "leave-out" strategy is also used in Tabellini (2020). See Table A.1 for the list of European origin countries and regions used to construct the shift-share instrument.

³²In fact, approximately 70% of the organizations affiliated with the AFL, and in existence before 1920, were founded in 1890 or after (Stewart, 1926).

³³For theoretical foundations, see Borusyak et al. (2022) and Goldsmith-Pinkham et al. (2020).

setting particularly suited to the use of shift-share instruments (Abramitzky et al., 2023; Tabellini, 2020). In particular, the trend-break in immigration created by WWI lowers the concern that the shift-share instrument may be correlated with shocks jointly affecting local conditions in U.S. counties and immigration patterns from European countries. Moreover, the WWI shock reduces worries about the design being invalidated by the serial correlation in migration flows from the same country to the same U.S. destination (Jaeger et al., 2018).

Instrument validity. Nevertheless, although the immigrant networks captured by $\alpha_{c,1890}^j$ predate the time period of the analysis, they may be endogenous with respect to the trajectory of the outcomes of interest. I deal with this concern in several ways. First, I augment the main specification by including interactions between year dummies and county characteristics that were correlated with immigrants' settlements (from each origin country) in 1890, and which may have had a time-varying effect on unionization across counties. In the preferred specification, such controls include: (i) the share of families in farming, (ii) the share of the population employed in manufacturing, (iii) the number of coal mines per capita, and (iv) an indicator for the presence of a railroad in the county. These controls account for the fact that both immigration and labor unions were concentrated in areas with better economic and employment opportunities (Abramitzky and Boustan, 2017; Taft, 1964). Counties with lower farming activity, substantial manufacturing and coal mining, and connections to the railroad network attracted more immigrants early on (Table A.2), and likely experienced greater union growth in the early 20th century.³⁴ Table 2 reports the first stage coefficients, introducing each control gradually, one at a time. Across all columns, actual and predicted immigration are positive correlated and all coefficients are statistically significant at the 1% level.

Second, I directly control for the size of the 1890 European immigrant population, interacted with year dummies. This implies that the effects of immigration are identified exploiting variation only in the ethnic composition of immigrant enclaves across counties, holding constant the size of their foreign-born populations. Since the instrument predicts higher immigration to counties with a larger stock of immigrants at baseline, by doing this I also address the concern that a larger 1890 immigrant population may itself have an independent and time-varying effect on unionization. Third, I include interactions between year dummies and the baseline share of immigrants from each European country, $a_{c,1890}^j$, to assuage concerns that the 1890 settlements of specific European groups across U.S. counties might be correlated with both the long-run trends in unionization and the migration patterns of those specific immigrants groups, in each decade between 1890 and 1920.

³⁴In Appendix B, I show that the results are robust to the inclusion of various county-level controls that could influence both the 1890 immigrant population and subsequent unionization (Table B.4). I also show that the findings are not dependent on the inclusion of any of these baseline controls (Table B.5)

Alternative instrument. In addition, I construct an alternative version of the instrument described in equation (2), where I replace the actual immigration flows from each country j with those predicted exploiting variation in weather shocks across European countries over time. This allows me to identify causal effects from the exogenous variation in the shocks, while allowing the exposure shares to be endogenous (Borusyak et al., 2022). I then interact them with the baseline shares of European immigrants from each country j to obtain the alternative instrument. Appendix B.1 describes its construction in more detail.

Matching and shift-share instrument. Finally, similarly to Bazzi et al. (2023), in Appendix B.2 I combine the shift-share instrument of equation (2) with a matching exercise. In particular, I select within-state county pairs with similar baseline presence of labor unions, as measured by the number of branches of the Knights of Labor in the late 19th century as a fraction of the county population.³⁵ Then, I re-estimate the 2SLS analysis also controlling for fixed effects for the county pairs interacted with year dummies.

I summarize all other robustness checks in Section 5.3, after presenting the main results.

5 Main Results

5.1 The Effect of Immigration on Unionization

In Table 3, I investigate the effects of immigration on the formation and growth of labor unions by estimating equation (1). I examine four unionization measures: an indicator for whether the county has any labor union (column 1); the (log) number of union branches (column 2);³⁶ union density, defined as the number of union members a fraction of the labor force (column 3);³⁷ and the average branch size, defined as the number of union members divided by the number of branches (column 4).³⁸ All regressions include county

³⁵As described in Section 2, the Knights of Labor were a federation of unions that was particularly active in the 1880s, and declined after 1890, when the AFL became the dominant federation of unions. For this exercise, I use data from Garlock (2009) to measure union presence as of 1890, when the AFL was only recently established and did not yet have substantial national presence (Foner, 1947).

³⁶Since this variable may take value zero if no union branch is observed, I apply the transformation $\log(1 + x)$ instead of $\log(x)$, where x is the number of branches. The results are very similar when using an inverse hyperbolic sine transformation instead.

³⁷Throughout the paper, union density is measured as the number of union members as a fraction of the total male labor force in nonfarm occupations, except for managers, proprietors, and private household service workers, as these groups were typically ineligible to unionize during this period (Stewart, 1926; Wolman, 1924). The results are unchanged when using alternative denominators in the definition of union density (Table B.9).

³⁸To maintain the same sample throughout the analysis, and for consistency with the other outcomes, this variable is set to zero if the county has no union branch (and, therefore, also no union members). The results are similar when limiting the sample to county-year observations with at least one union branch. See Section 5.2 for a discussion on the effects at the extensive and intensive margins of unionization.

and year fixed effects, and interactions between year dummies and the baseline share of population in farming and in manufacturing, the number of coal mines per capita, and an indicator for the presence of a railroad in the county (as discussed in Section 4.2). Panel A presents the OLS estimates. All coefficients are positive and statistically significant. This suggests that counties that received more immigration were also more likely to display higher levels of unionization.

Panels B and C show the reduced form and the 2SLS estimates. The F-stat for weak instruments, reported at the bottom of the table, is always well-above the conventional levels, and indicates that the instrument is strong. All the point estimates are positive and statistically significant at the 5% (column 1) or 1% (columns 2 to 4) level. The 2SLS estimates imply that a 4.3 percentage point (one standard deviation) increase in the share of recent immigrants causes a 10.7 percentage point (24% relative to the mean) higher probability that the county has any union (column 1); a 19% increase in the number of union branches (column 2),³⁹ a higher share of unionized workers by 1.3 percentage points, or 35% relative to the sample mean (column 3); and 22 more members per branch, or 45% relative to the sample mean (column 3). A back-of-the-envelope calculation, done by comparing the actual level of union density measured in the data to the one predicted by the 2SLS estimates, reveals that in the absence of immigration, the average union density between 1900 and 1920 would have been 23% lower overall.

The difference between OLS and 2SLS estimates indicates that the former are biased downwards, and suggests that European immigrants selected areas where unionization was growing more slowly. This might have happened because, during this period, the vast majority of labor unions actively discriminated against immigrants, precluding them from joining their ranks and the occupations they represented (Asher, 1982). Consistent with the historical evidence, Table A.5 shows that there is a negative and statistically significant relationship between all four measures of unionization and immigration flows. Moreover, the instrument addresses any attenuation bias caused by measurement error in the independent variable, which would lead to downward-biased OLS estimates. Finally, the instrument identifies a local average treatment effect (LATE) for counties that received more European immigrants because of country-of-origin networks, and not because of economic or political characteristics of the destination county. If these immigrants were more likely to drive an increase in unionization, this would contribute to the OLS coefficients being smaller than the 2SLS estimates.

³⁹Given that the dependent variable of column 2 is log-transformed, the magnitude of the coefficient can be calculated as follows: $\% \Delta y = 100 \cdot (e^\beta - 1) = 100 \cdot (e^{4.004 \times 0.043} - 1) \approx 19\%$.

5.2 Effect on the Intensive and Extensive Margins

The results presented in Table 3 do not differentiate between an increase along the extensive or the intensive margin of unionization. In other words, they show that counties receiving larger shares of immigrants are more likely to have unions (column 1) and experience an increase in the number of union branches and members (columns 2 to 4). However, the findings do not clarify whether this is driven solely by the establishment of unions in new areas or if immigration also strengthens organized labor in already unionized labor markets.

To explore this further, I first restrict the estimation sample to counties that had unions in every decade between 1900 and 1920. This approach allows for a more specific investigation of the results along the intensive margin. All coefficients, shown in Panel A of Table 4, are positive and statistically significant. Specifically, a 4.8 percentage point (one standard deviation) increase in the share of immigrants leads to a 34% increase in the number of branches, a 2.7 percentage point rise in union density (a 31% increase relative to the mean), and 36 more members per branch (a 32% increase relative to the mean). Similarly, to focus on the extensive margin, I re-estimate equation (1) for counties that did not consistently have unions between 1900 and 1920, with the results presented in Panel B of Table 4. Again, all coefficients are positive and statistically significant.

These two additional sets of estimates indicate that immigration positively impacted unionization along both the intensive and extensive margins. New counties saw the establishment of labor unions, while those with an existing labor movement experienced an expansion in its size.

5.3 Summary of Robustness Checks

I perform several exercises to verify the robustness of the findings. They are summarized visually in Figure 7 and Figure 8, with more details and formal estimates presented in Appendix B.

I show that the results are unchanged when using a version of the instrument that relies on weather shocks in each European country for the period 1890–1920 to predict the flows of European immigration (Table B.2).⁴⁰ This alternative identification strategy relies on the observation that the validity of shift-share instruments can be achieved from the exogeneity of the shocks (Borusyak et al., 2022).

Next, building on Bazzi et al. (2023), I combine the shift-share instrument with a matching strategy, which selects within-state county pairs with the closest number of labor unions in 1890 as a fraction of the county population (Table B.3).

⁴⁰This alternative version of the instrument builds on previous work from Sequeira et al. (2020) and Tabellini (2020).

Moreover, I verify that the results are robust to the inclusion of several county characteristics that are likely correlated with the 1890 settlements of European immigrants and the subsequent development of labor unions, measured at baseline and interacted with year dummies (Table B.4). These include the share of the total immigrant and Black population, the share of the labor force in the largest industries, the share of the labor force in highly unionized industries and by skill level, the average occupational income score, the growth rate of the manufacturing output, the share of land used for farming, and the vote share for the Democratic Party in presidential elections.

Further, I show that the findings are unchanged when using alternative baseline specifications, such as not controlling for any baseline characteristics or including state by year fixed effects (Table B.5); clustering standard errors at the State Economic Area (SEA) level, using [Conley \(1999\)](#) standard errors to account for spatial correlation, or applying the correction for shift-share estimators proposed by [Adao et al. \(2019\)](#) (Table B.6); dropping potential outliers (Table B.7); using alternative definitions of the independent and dependent variables (Table B.8 and Table B.9); extending the analysis to an unbalanced sample of counties or excluding the South from the estimation sample (Table B.10); performing the analysis at the State Economic Area (SEA) level (Table B.11); and using different methods for constructing unionization data (Table B.12 and Table B.13).

I also re-estimate the preferred specification of Table 3 while interacting – one at a time – the initial shares of each immigrant group in the county, i.e., $\alpha_{c,1890}^j$ in equation (2), with year dummies (Figure B.2). This exercise is aimed at reducing the concern that combinations of counties and of immigrants from specific European countries might be driving the results by absorbing most of the variation in the data ([Goldsmith-Pinkham et al., 2020](#)).⁴¹

Finally, I check for the absence of pre-trends by regressing the pre-period change of a set of unionization, population, and economic outcomes on the average 1900–1920 immigration predicted by the instrument (Table B.14). The fact that all these coefficients are not statistically significant indicates that, before 1890, European immigrants did not settle in counties that were already undergoing changes in union presence or other economic variables.

6 Mechanisms

The results shown so far indicate that counties that received larger inflows of European immigrants between 1890 and 1920 experienced a larger increase in unionization. In this section, I explore the mechanisms that are driving the positive effect of immigration on the emergence and growth of organized labor.

⁴¹This robustness check also deals with the potential concern that such shares may not be independent of cross-county pull factors related to the initial immigrants' country of origin.

6.1 Economic Motivations

Reactions of existing workers. As described in Section 2, unions have long been concerned with labor supply expansions, fearing that an influx of new workers would lower wages, worsen working conditions, and create job scarcity. Scholars have argued that these concerns led existing workers to organize their workplaces and restrict access to the labor market (Mink, 1986; Olzak, 1989).⁴² The economic threats posed by immigration heightened workers' incentives to unionize and limit immigrants' entry into the labor force. The positive effects presented in Table 3 are consistent with this hypothesis.

At the same time, immigration inundated urban labor markets with inexpensive laborers seeking employment. This, in turn, increased employers' bargaining power by reducing their cost to break strikes and replace workers willing to unionize (Asher, 1982; Mink, 1986; Olzak, 1989). This process was facilitated by the political and legal framework of the period, when the law did not grant workers the right to organize and courts often sided with employers in disputes over the dismissal of unionizing or striking employees (Foner, 1947; Taft, 1964).

Given these opposing forces, unionization efforts by existing workers in response to immigration should be more likely to succeed in occupations with entry barriers, such as those requiring minimum levels of human (or physical) capital. Although immigrants were perceived as a threat to employment and wages across all occupations (Asher, 1982; Mink, 1986; Olzak, 1989), they could not *immediately* replace incumbent workers in these jobs. This dynamic should put existing workers in a stronger position to organize and limit the future entry of immigrants into their roles. Similarly, employers lacking a readily available pool of replacement workers should be less likely to resist unionization efforts and more inclined to accommodate their employees' demands to form a union.

I leverage differences in the skill requirements across occupations to test whether immigration had heterogeneous effects on skilled and unskilled workers.⁴³ The estimates, reported in Table 5, indicate that immigration positively impacted all four unionization measures among skilled workers. Counties with higher shares of recently arrived immigrants saw increases in the probability of having any union, the number of union branches, the share of the workforce that was unionized, and the number of union members per branch. By contrast, immigration did not affect the unionization of unskilled workers. These findings support the hypothesis that barriers to entering an occupation provided incumbent workers with an advantage in their efforts to establish and maintain a labor union.

⁴²Two of the methods most commonly used by unions to control the access to certain occupations were imposing union membership as a condition of employment and regulating the terms of apprenticeships (Ignatiev, 1994).

⁴³The classification of occupations based on their skill levels follows Katz and Margo (2014). Skilled occupations include professional, technical, clerical, sales, and craft workers. Unskilled occupations include operatives, laborers, and service workers.

Similarly to Table 4 (Panel A), Table A.3 restricts the estimation sample to a balanced set of counties that had skilled (Panel A) and unskilled (Panel B) unions in every decade between 1900 and 1920. The coefficients indicate that immigration positively affected skilled unionization also along the intensive margin, increasing the share of unionized workers in always unionized counties.

Taken together, these findings show that immigration fostered the emergence and development of labor unions that represented skilled workers. This is consistent with this group of workers having a higher bargaining power with their employers, as their skills provided an entry barrier into their occupations and made them less easily replaceable in the short run. Moreover, these findings indicate that skilled unionization increased as a consequence of immigration both along the intensive and extensive margin.

Exposure to the immigrants' competition. One potential alternative explanation for the results just presented is that unions representing skilled workers were able to develop due to an absence of competition between new and existing workers, rather than in reaction to the economic threats brought by the immigrants. In Figure 9, I show suggestive evidence in contrast with this hypothesis. I report the prevailing occupations among the immigrants that entered the United States in each decade between 1890 and 1920. Both unskilled (e.g., mine laborers) and skilled (e.g., carpenters, machinists) occupations feature among the most frequent ones.

To formally estimate the effect of immigrant labor market competition on unionization, I interact the main regressor of interest from equation (1) with a time-varying measure of a county's exposure to immigrants' competition for jobs.⁴⁴ This measure consists of two terms. The first is given by the number of immigrant workers in each occupation o who entered the United States (net of those that settled in county c) between $t - 10$ and t , as a fraction of the total immigrants in the labor force who entered the United States between $t - 10$ and t . The second is a weight, represented by the share of U.S.-born workers in county c and occupation o at the beginning of that decade:⁴⁵

$$Competition_{c,t} = \sum_o \frac{Imm^o_{-c,t}}{Imm^{LF}_{-c,t}} \times \frac{USborn^o_{c,t-10}}{USborn^{LF}_{c,t-10}} \quad (3)$$

The intuition behind this measure is simple: counties where U.S.-born employment (at the beginning of the decade) is concentrated in occupations which are prevalent among recently arrived immigrants are more exposed to labor market competition.

In Table 6, I show the results separately for skilled (Panel A) and unskilled (Panel B)

⁴⁴The logic behind this measure resembles the one employed, among others, by Autor et al. (2020) for import competition from China across U.S. labor markets and by Alsan et al. (2020) for Irish immigrants' labor competition in the 1850s in Massachusetts.

⁴⁵Due to the unavailability of the 1890 full-count Census, the number of U.S.-born workers in each occupation at the beginning of the 1890s refers to the year 1880. The results are robust to restricting the sample to the decades starting in 1900 and 1910 only.

workers, where the main regressor of interest is interacted with a standardized version of the measure presented in equation (3). In Panel A, the uninteracted estimates are all positive and statistically significant. Remarkably, all the coefficients of the interactions are also statistically significant. These findings indicate that counties more exposed to the immigrant labor market competition in skilled occupations experienced larger growth in skilled unionization. In contrast, estimates in Panel B show negative coefficients for the interaction term. These results show that, among unskilled workers, increased labor market competition hampered the growth of labor unions instead.

In sum, these findings provide additional evidence for the hypothesis that increased labor competition caused by immigration contributed to the growth of labor unions. Moreover, they indicate that competition fostered unionization only among skilled workers, while it slowed down union growth among the unskilled labor force. This is consistent with the fact that immigrants were a better and more immediate substitute for unskilled laborers, whose bargaining power got weakened by the increased availability of replacement workers and strikebreakers.

6.2 Social Motivations

The results shown so far have examined the purely economic channels that strengthened labor unions as a consequence of immigration. However, one may expect social concerns (e.g., opposition to cultural change) to provide a further incentive for workers to organize and exclude newcomers from the labor market. This possibility is motivated by the nativist rhetoric adopted by the labor movement in this period, and by its vigorous support for immigration restrictions throughout the 20th century (Goldin, 1994; Mink, 1986). At the same time, prominent research has linked the cultural heterogeneity of the U.S. workforce to the country's weak labor movement (Alesina and Glaeser, 2004). In this section, I explore the role of these factors on the development of organized labor.

Discrimination against culturally distant immigrants. As described in Section 2, not all European immigrants were perceived in the same way. The main worries of the labor movement – and of the nativist movement, more generally – were caused by individuals arriving from Southern and Eastern Europe, who were more culturally distant from U.S.-born residents than the ones who had migrated in large numbers before the 1890s: they spoke non-Germanic languages, were not Protestant, were considered unwilling to assimilate into the American society, and were not responsive to the discipline of labor unions (Goldin, 1994; Higham, 1955; Taft, 1964). If increased unionization was caused in part by xenophobic reactions, the effects should be more prominent in places that received larger shares of more culturally distant immigrants. To test this idea, I estimate

$$y_{ct} = \beta_1 Imm_{ct}^{SE} + \beta_2 Imm_{ct}^{NW} + \theta_c + \tau_t + X_t + u_{ct} \quad (4)$$

where Imm_{ct}^{SE} is the fraction of immigrants from Southern or Eastern Europe, and Imm_{ct}^{NW} is the one of immigrants from Northern or Western Europe. Equation (4) is estimated using two separate instruments, one for each group, constructed by summing the predicted immigration (as described in Section 4.2) from each sending region. I present the results in Table 7. As expected, larger increases in unionization are caused by the inflow of immigrants from Southern and Eastern Europe.⁴⁶

Heterogeneity by attitudes towards immigration. However, the previous result may conflate economic and cultural concerns, to the extent that immigrants from those areas may have also had lower wage expectations, and made coordination within unions harder due to their higher illiteracy rates and larger linguistic distance than immigrants from Northern and Western Europe. To further explore this channel, I test whether the effects are stronger in counties with worse attitudes towards immigration. In the absence of a direct measure, I use two proxies that likely reflect a county's higher hostility towards immigrants. The first is the historical vote share for the Know Nothing Party, a nativist political party that ran on an anti-Catholic and anti-Irish platform in the mid-1850s (Alsan et al., 2020). The second is a measure of residential segregation between U.S.-born and European immigrants.⁴⁷ Since residential segregation usually arises either from collective action to exclude minorities or from individuals from the majority group moving away from ethnically mixed neighborhoods (Boustan, 2010, 2013), this characteristic likely reflects higher levels of discrimination against immigrants.

The results are reported in Table 8, where the main independent variable is interacted with indicators for whether a county has a high or low historical vote share for the Know Nothing party (Panel A) or residential segregation at baseline (Panel B).⁴⁸ Using either proxy, the findings indicate that immigration strengthened organized labor more prominently in counties with higher resentment towards immigration.

Altogether, these results suggest that non-economic motives also contributed to the expansion of labor unions. Unionization occurred more prominently in counties that received larger shares of culturally distant immigrants, namely those from Southern and Eastern Europe. Moreover, immigration strengthened the American labor movement more in counties that harbored less favorable attitudes towards immigration.

⁴⁶The results are unchanged when separately estimating immigration from Protestant and non-Protestant countries (Table A.7).

⁴⁷I construct an index of residential segregation of European immigrants, building on the procedure used in Logan and Parman (2017). The index is constructed using 1880 full-count U.S. Census data, in order to avoid endogeneity concerns. Measuring it after 1890, the baseline year of the instrument, may qualify as a "bad control" (Angrist and Pischke, 2009). For more details on its construction, see Appendix D.

⁴⁸In Table 8, low (high) is defined as below (above) the first tercile of the sample distribution. Table A.8 reports analogous results by showing the differential effects for counties above vs. below the first tercile, and Table A.9 by interacting the main independent variable with indicators for each tercile.

6.3 Ruling Out Alternative Explanations

Immigrant-driven unionization. One alternative explanation for the results is that immigrants may have joined or created labor unions at greater rates than U.S.-born workers. Although data on the individual union members are not available, I exploit the information on the local union representatives described in Section 3 to gauge the ethnic composition of their branches. Union delegates can be considered leaders of the organizations they represented, as they acted as spokespeople of their local branch at the state and national conventions, and were in charge of making decisions in the name of the members who elected them. For these reasons, their ancestry can be intended as reflecting the ethnic composition of their branch.

As a first step, I use the last names of the delegates to infer their origins, using historical de-anonymized full-count U.S. Census data.⁴⁹ Panel A of Figure A.4 shows that, as expected, most of the union leaders were U.S.-born. In Panel B, I break down the shares of delegates by ancestry. Almost all delegates had ancestry from Northern or Western Europe, while very few came from Southern or Eastern Europe.

Although the share of U.S.-born delegates increased – and that of Europeans decreased – over time at the national level, it may still be the case that counties that received more immigrants experienced an increase in the proportion of European leaders. If, for example, newly arrived immigrants joined labor unions *en masse*, we would expect to see an increase in the share of European delegates, as the newcomers would likely obtain the voting power to elect them. To test this, I use the proportion of leaders with last names prevalent among U.S.-born people and Europeans, computed at the county level, as dependent variables in equation (1). The coefficients, plotted in Panel A of Figure A.5, indicate that the inflow of immigrants did not increase the proportion of leaders with immigrant last names. The coefficients on the left, estimated on the whole sample of counties, show that immigration increased the share of U.S.-born leaders more than that of immigrants. The ones on the right, computed on the counties where I observe at least a delegate in every year – although imprecisely estimated – suggest that immigration caused a redistribution of delegates in favor of the U.S.-born.⁵⁰

These findings confirm the anecdotal and historical evidence that the observed increase in unionization of this period was not caused by a larger participation of immigrant laborers, but rather by U.S.-born workers (Mink, 1986; Taft, 1964), who maintained the control of labor unions throughout the first 20 years of the 20th century.

⁴⁹I describe the procedure I use in Appendix C. An alternative approach would be to link individuals to the Census directly, based on the full name. However, most of the unions' convention proceedings only report the delegates' last name and initials, substantially limiting the number of records that could be matched with this method. Moreover, in no occasion do I observe union leaders' year of birth (or age), a key variable usually employed to match people to Census data.

⁵⁰Analogous conclusions hold when looking at the proportion of union leaders with either Northern/Western European or Southern/Eastern European ancestry (Panel B of Figure A.5).

Previous exposure to labor unions or socialist ideologies. A second possibility is that immigrants coming from European countries that already had well-developed labor unions by the end of the 20th century, or where socialist ideas were more popular, may have brought into the United States their ideas and experience from their home country, and, in turn, contributed to the growth of unionization in their destination counties. This explanation would be in line with existing work arguing that Europeans who migrated to the United States between 1910 and 1930 promoted spillover of ideologies to U.S.-born individuals ([Giuliano and Tabellini, 2022](#)). Although the results just presented already suggest that immigrants' participation in labor unions did not increase upon Europeans' arrival, I test this hypothesis formally, estimating the effect of immigration separately for immigrants coming from countries with or without strong labor unions (Table [A.10](#)) and with higher or lower support for socialist parties (Table [A.11](#)).⁵¹ The results rule out this possibility. The coefficients of the share of immigrants from the U.K. and Ireland, the only countries with a strong labor movement at the turn of the 20th century, and from countries with higher support for socialist parties, are never statistically significant; on the contrary, almost all the coefficients for the share of immigrants from the rest of Europe are positive and statistically significant.

Other economic channels. Another possibility is that the growth in unionization was driven by differential economic expansion – or contraction – experienced by counties receiving larger shares of immigrants. In Table [A.12](#), I show that this is not the case. Immigration had no effect on economic indicators such as the labor force participation rate or the total manufacturing output (either divided by the manufacturing labor force in the county or as a proportion of national output). Furthermore, immigration did not increase the share of the labor force in skilled occupations, ruling out the possibility that the observed effects were driven by the expansion of sectors requiring skilled labor due to immigrant inflows (for example, if immigration had boosted demand for carpenters and construction workers to support new housing development).

This discussion suggests that the results are unlikely to be driven by the preferences or ideologies brought by immigrants to the United States, or by other effects of immigration on the local economy.

7 Implications and Discussion

In this section, I provide and discuss some implications related to the immigration-induced unionization in skilled workers' unions. Although not all these findings can

⁵¹I use data from [Crouch \(1993\)](#) to classify European countries into these two groups. Appendix [E](#) provides more information on the data and on labor unions in Europe during this period. The data for the vote shares obtained by socialist parties come from [Austrian National Library \(2024\)](#), [Mackie and Rose \(2016\)](#), and [Nohlen and Stöver \(2010\)](#). Appendix [F](#) reports more detailed information on the data sources and the socialist vote shares by country for this time period.

be interpreted as causal, they still provide insights on the short- and medium-run trends associated with a higher presence of organized labor.

Effects on U.S.-born workers' outcomes. A question unexplored thus far in the paper is whether immigration had any effect on the distribution of occupations among U.S.-born workers. In particular, one may expect U.S.-born workers to turn to unionized occupations, to safeguard themselves from the perceived threats of immigrant competition and cultural differences. I explore this possibility by testing whether immigration had a different impact depending on whether a certain occupation had a positive union membership in the county or not. More specifically, I restrict the attention to occupations within the jurisdiction of the AFL unions, and compute the county shares of U.S.-born workers in occupations with and without local union representation. The results are presented in Table A.13. Consistent with the hypothesis, immigration increased the share of the U.S.-born labor force in skilled occupations that had union representation in the county. On the other hand, the effect on the share of U.S.-born in occupations with no union representation is negative and not statistically significant. Although this explanation is consistent with the historical narrative of the period (Mink, 1986), stating that U.S.-born workers resorted to skilled (craft) unions in response to immigration, these results are also consistent with a different – and potentially complementary – interpretation. In particular, it is possible that union representation may have occurred simultaneously or as a consequence of U.S.-born workers moving to those occupations. Data limitations prevent me from exploring the exact timing. However, the fact that the employment of the U.S.-born did not increase overall across all skilled occupations – but only in those with local union presence – assuages concerns that the observed growth in unionization may be a mere result of an overall employment shift towards skilled occupations.

In addition, consistent with existing evidence in both historical settings (Abramitzky et al., 2023; Tabellini, 2020) and recent times (Card, 2001b, 2005, 2009; Foged and Peri, 2016; Ottaviano and Peri, 2012), immigration did not have negative effects on the labor market outcomes of domestic workers, which I measure with the labor force participation rate and the (log) occupational income score (Table A.14).⁵² In light of the increased unionization caused by immigration that this paper documents, these results suggest that labor unions may have mediated the potentially adverse economic consequences on domestic workers of the immigration-induced labor supply expansion.

Persistence of unionization. Additionally, I investigate whether the effects of early 20th-century immigration on unionization, which are documented for the first time in this paper, persist into the present. To align with the current measures of unionization from Macpherson and Hirsch (2023), I aggregate the data at the metropolitan-area level and employ the same shift-share instrument described in Section 4.2 to examine the impact of

⁵²The full-count Census data of this period do not consistently report information on employment status (only in 1910), and information on wages was first collected in 1940 (Ruggles et al., 2021).

historical immigration on average private sector union density over the first two decades of the 21st century, a full century after the period studied. Remarkably, metropolitan areas that experienced larger waves of immigration still exhibit higher union density today (Table A.15). According to the 2SLS estimates, a four percentage point (one standard deviation) increase in historical immigration leads to an almost three percentage point increase in unionized workers today, or roughly 34% of the sample mean. Consistent with the development of unions in the first two decades of the 20th century, which were primarily concentrated in the construction sector rather than manufacturing, past immigration has a lasting positive effect on today's union density in the former sector (48% increase relative to the mean), but no significant effect on unionization levels in the latter. This suggests that the conditions fostering the early rise of labor unions in the 1900s provided the labor movement with a lasting advantage, particularly in sectors like construction, which has endured over the decades.

Unions and inequality. Another central economic question that arises from the findings of this paper concerns the consequences of unionization on inequality. Recent evidence ([Farber et al., 2021](#)) has documented a causal impact of labor unions in reducing inequality for most of the 20th century, combining national and state-level survey data on unionization from the mid-1930s onwards. I use data on wages from the U.S. Census of 1940 – the first year in which such information was collected – to compute measures of wage inequality at the county level, and investigate the correlation between them and measures of unionization in 1920 – the last year in the sample. Following the literature ([Autor et al., 2008](#)), I measure inequality as the log wage differentials for full-time, full-year workers computed at the following percentiles: 90 to 10; 90 to 50; and 50 to 10.⁵³ I present the results in Table A.16. The coefficients display a negative correlation between the presence of labor unions in the county (and the size of their membership) and wage inequality. Although not causal, these results are consistent with existing studies documenting labor unions' contribution in reducing inequality ([Collins and Niemesh, 2019](#); [Farber et al., 2021](#)), and suggest that unions may have done so already in the first four decades of the last century.

8 Conclusion

Despite the enduring relevance of labor unions throughout history and in contemporary society, we lack rigorous empirical evidence regarding the determinants of their origins and early growth. In this paper, I investigate the effects of a large labor supply increase, represented by the mass immigration of the early 20th-century United States, on the development of organized labor. I find that immigration strengthened the labor movement

⁵³As in [Autor et al. \(2008\)](#), I exclude self-employed workers, and construct weekly wages focusing on men ages 16–64 years old who worked for at least 40 weeks and at least 35 hours per week.

by increasing the probability that a county had any union, the share of unionized workers, the number of union branches, and their average membership. The findings are consistent with economic as well as social motivations: unions grew due to workers' reactions to the increased labor competition brought by immigrants and to concerns about cultural change.

The findings of this paper quantitatively identify immigration as a novel driver of unionization during the early days of the American labor movement. The estimates imply that in the absence of immigration, the average union density between 1900 and 1920 would have been 23% lower. They also shed light on an unexplored consequence of immigration: the strengthening of institutions that protect incumbent workers' status in the labor market. Notably, this study also deepens our understanding of the broader implications of immigration. It suggests that individuals' reactions to immigration are not confined to political shifts toward conservative parties or the advocacy of anti-immigration policies, as previously emphasized in existing research. Instead, immigration can also foster the development of self-organized institutions with broad political impact, such as labor unions.

While the specific quantitative estimates presented in this paper may pertain to the unique context under examination, its implications carry wider-reaching significance. They underscore the role played by both economic and cultural considerations in shaping labor market dynamics and institutions, suggesting that effective labor market policies should take all these aspects into account. Furthermore, the study provides valuable insights into the factors contributing to the recent resurgence of the labor movement, particularly following a period of challenges for private sector labor unions. The numerous successes achieved by organized labor in various sectors such as automotive, transportation, education, and services over the past few years, as well as the emergence of unionization efforts in previously unorganized multinational corporations like Amazon and Starbucks, encourage new considerations. For example, they suggest that this renewed interest in labor unions may also reflect concerns about job scarcity, arising from a confluence of heightened competition in the labor market (due to significant immigration flows) and rapid technological advancements.

Importantly, the relevance of these findings extends beyond the United States. These results speak to the context of many European countries experiencing a surge in immigration while labor unions continue to wield economic and political influence. Additionally, these findings hold significance for industrializing and recently industrialized countries whose economic transformations parallel those of early 20th-century America. They may also apply more broadly to settings where institutional safeguards for workers' rights to organize and collectively bargain are limited.

Finally, this study paves the way for several promising avenues of future research. First, it prompts further investigation into the drivers of organized labor's growth across

different economic contexts and time periods. Second, the comprehensive data collected for this paper will allow researchers to investigate several other questions, such as the long-term consequences of the early 20th-century unionization on the American experience of immigrants, and on the evolution of the U.S. economy, more generally.

Tables

Table 1: Summary Statistics

	Obs.	Mean	St. Dev.
<i>Panel A: Unionization</i>			
Any Union Present	2,628	0.44	0.50
Number of Union Branches	2,628	2.62	5.40
Union Density (Members / Labor Force)	2,628	0.04	0.08
Union Members per Branch	2,628	48.26	73.51
<i>Panel B: Demographics</i>			
Share of Urban Population	2,628	0.30	0.27
Share of Immigrant Population	2,628	0.09	0.10
Share of European Immigrant Population	2,628	0.08	0.08
Share of European Imm. Pop. (<10 years in U.S.)	2,628	0.02	0.03
<i>Panel C: Labor Force (men ages 16–64)</i>			
Total Labor Force	2,628	14,777.32	44,231.97
Labor Force Participation Rate	2,628	0.91	0.04
Share of U.S.-Born Labor Force	2,628	0.86	0.15
Share of European Immigrant Labor Force	2,628	0.12	0.12
<i>Panel D: Baseline Characteristics (in 1890)</i>			
Share of European Immigrant Population	876	0.10	0.10
Share of Population in Farming	876	0.45	0.19
Share of Population in Manufacturing	876	0.03	0.04
Number of Coal Mines (per 1,000 people)	876	0.14	0.46
Presence of Railroad	876	0.95	0.22

Notes: The table presents summary statistics for the counties in the main estimation sample described in Section 3. The measures in Panel A, winsorized at the 1% to remove outliers, come from the digitized records of the AFL-affiliated unions described in Section 3.1. The information in Panel B and Panel C is from the full-count Census of Population of 1900, 1910, and 1920 (Ruggles et al., 2021); the data in Panel D are from the 1890 Census of Population (Haines, 2010), the 1890 Census of Agriculture (Haines et al., 2018), the 1890 Report on Mineral Industries (Day, 1892), and the database on the expansion of the railroad network compiled by Atack (2016).

Table 2: First Stage of the Instrumental Variable Estimation

	<i>Dependent variable: Share of Immigrants</i>				
	(1)	(2)	(3)	(4)	(5)
Predicted Share of Immigrants	0.336*** (0.037)	0.273*** (0.033)	0.274*** (0.033)	0.272*** (0.033)	0.271*** (0.034)
Observations	2628	2628	2628	2628	2628
Dep. var. mean	0.028	0.028	0.028	0.028	0.028
Indep. var. mean	0.030	0.030	0.030	0.030	0.030
KP F-statistic	80.67	67.89	67.76	67.59	65.27
Share of Farming in 1890	No	Yes	Yes	Yes	Yes
Share of Manufacturing in 1890	No	No	Yes	Yes	Yes
Number of Coal Mines (per 1,000 ppl.) in 1890	No	No	No	Yes	Yes
Presence of Railroad in 1890	No	No	No	No	Yes

Notes: The observations are at the county-year level. The table reports the first stage of the instrument described in Section 4.2. The dependent variable is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The main regressor of interest is the predicted number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the 1890 male population in the county. All regressions include county and year fixed effects. The following controls, measured in 1890 and interacted with year dummies, are also included: the share of families in farming (from column 2); the share of population in manufacturing (from column 3), the number of coal mines per 1,000 people (from column 4), and an indicator for the presence of a railroad in the county (column 5). KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table 3: The Effect of Immigration on Organized Labor

	<i>Dependent variable:</i>			
	Any Union Present (1)	Number of Union Branches (2)	Union Density (Members / LF) (3)	Union Members per Branch (4)
<i>Panel A: OLS</i>				
Share of Immigrants	0.619* (0.347)	1.869*** (0.473)	0.105** (0.050)	158.400*** (55.378)
<i>Panel B: Reduced Form</i>				
Pred. Share of Immigrants	0.673** (0.285)	1.085*** (0.383)	0.082*** (0.029)	136.673*** (41.171)
<i>Panel C: 2SLS</i>				
Share of Immigrants	2.485** (1.160)	4.004*** (1.520)	0.302*** (0.106)	504.600*** (158.205)
Observations	2,628	2,628	2,628	2,628
Dep. var. mean	0.444	2.621	0.037	48.258
Indep. var. mean	0.028	0.028	0.028	0.028
KP F-statistic	65.27	65.27	65.27	65.27

Notes: The observations are at the county-year level. The dependent variables are: an indicator for whether the county has any labor union (column 1); the log of one plus the number of union branches (column 2); union density, defined as the number of union members divided by the total male nonfarm labor force (column 3); and the number of members per branch, or zero if the county has no union branch (column 4). The mean of the dependent variable in column (2) reflects the average number of union branches, not the log-transformed value. Panel A shows OLS estimates, where the regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. Panel B shows reduced form estimates, with the instrument described in Section 4.2. Panel C shows 2SLS estimates. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table 4: The Effect of Immigration on Organized Labor – Intensive and Extensive Margin

	<i>Dependent variable:</i>			
	Any Union Present (1)	Number of Union Branches (2)	Union Density (Members / LF) (3)	Union Members per Branch (4)
<i>Panel A: Intensive Margin</i>				
Share of Immigrants	6.020* (3.309)	0.560** (0.234)	745.757** (315.537)	
Observations	828	828	828	
Dep. var. mean	7.332	0.087	112.678	
Indep. var. mean	0.042	0.042	0.042	
KP F-statistic	21.07	21.07	21.07	
<i>Panel B: Extensive Margin</i>				
Share of Immigrants	3.288** (1.508)	3.805** (1.625)	0.231** (0.113)	439.922** (173.046)
Observations	1,800	1,800	1,800	1,800
Dep. var. mean	0.188	0.454	0.014	18.625
Indep. var. mean	0.021	0.021	0.021	0.021
KP F-statistic	46.56	46.56	46.56	46.56

Notes: The observations are at the county-year level. In Panel A, the sample is restricted only to counties that have some union presence in every year they are observed. In Panel B, the sample is restricted only to counties that do not have union presence in every year they are observed. The dependent variables are: an indicator for whether the county has any labor union (column 1); the log of one plus the number of union branches (column 2); union density, defined as the number of union members divided by the total male nonfarm labor force (column 3); and the number of members per branch, or zero if the county has no union branch (column 4). The mean of the dependent variable in column (1) reflects the average number of union branches, not the log-transformed value. The instrument used to predict it is described in Section 4.2. The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table 5: Heterogeneous Effects by Workers' Skills

SW F-statistic (Sh. of Imm. x Competition)	87.22	87.22	87.22	87.22

Notes: The observations are at the county-year level. The dependent variables are: an indicator for whether the county has any labor union (column 1); the log of one plus the number of union branches (column 2); union density, defined as the number of union members divided by the total male nonfarm labor force (column 3); and the number of members per branch, or zero if the county has no union branch (column 4). The mean of the dependent variable in column (2) reflects the average number of union branches, not the log-transformed value. In Panel A, the dependent variables refer to skilled workers; in Panel B, to unskilled workers (as detailed in Section 6). The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. Competition is a standardized measure of immigrants' labor market competition, based on the prevailing occupations (skilled in Panel A; unskilled in Panel B) among the U.S.-born workers in the county at the beginning of each decade and among the immigrants entering all other U.S. counties during that decade, as detailed in Section 6. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

SW F-statistic (High V)	61.10	61.10	61.10	61.10

Notes: The observations are at the county-year level. The dependent variables are: an indicator for whether the county has any labor union (column 1); union density, defined as the number of union members divided by the total male labor force in occupations represented by the American Federation of Labor (column 2); the log number of union branches (column 3); or, the average branch size, defined as the number of union members divided by the number of branches or zero if the county has no labor union (column 4). The mean of the dependent variable in column (2) reflects the average number of union branches, not the log-transformed value. The regressor of interest is the number of European immigrants (men 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. In Panel A, Share of Immigrants is interacted with indicators for whether the county has a low (first tercile) or high (second or third tercile) historical vote share for the Know-Nothing party (see Section 6 for more details). In Panel B, Share of Immigrants is interacted with indicators for whether the county has low (first tercile) or high (second or third tercile) residential segregation at baseline (see Section 6 and Appendix D for more details). All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. SW F-statistic refers to the Sanderson-Windmeijer F-statistic of the instruments in the two separate first-stage regressions. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

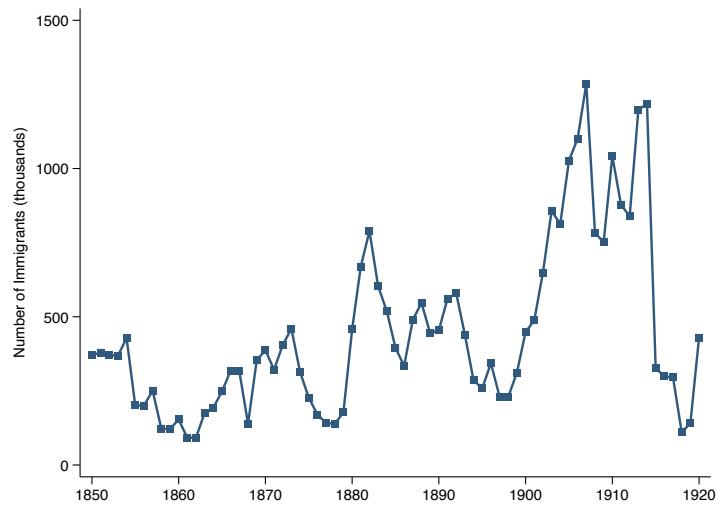

Figures

Figure 1: Estimates of Total Union Membership, 1880–1920

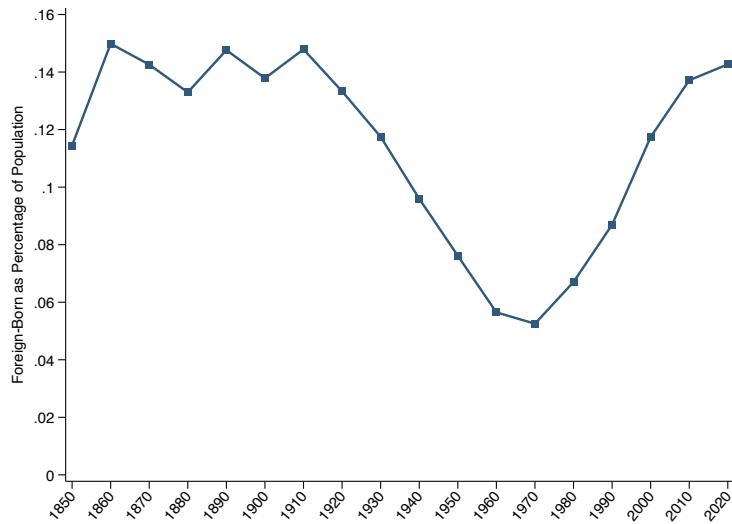

Notes: The figure shows the total number of union members in the U.S., between 1880 and 1920. Source: [Freeman \(1998\)](#).

Figure 2: Annual Inflow of Immigrants, 1850–1920

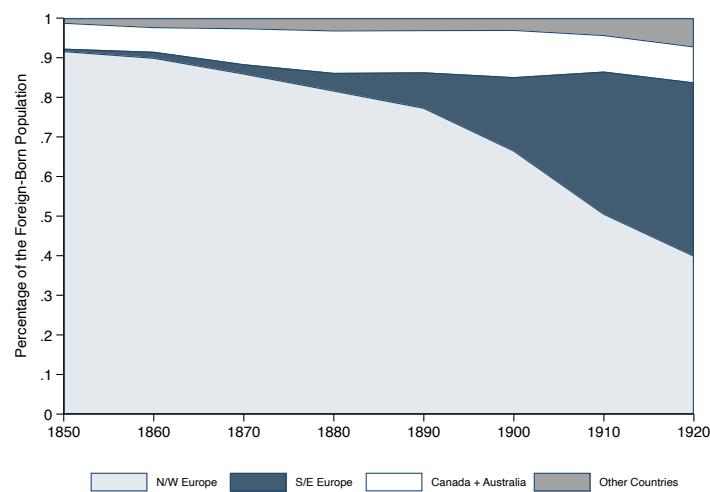

Notes: The figure shows the total number of immigrants to the United States, between 1850 and 1920. Source: Immigration Policy Institute.

Figure 3: Foreign-Born Stock as a Percentage of the U.S. Population, 1850–2020

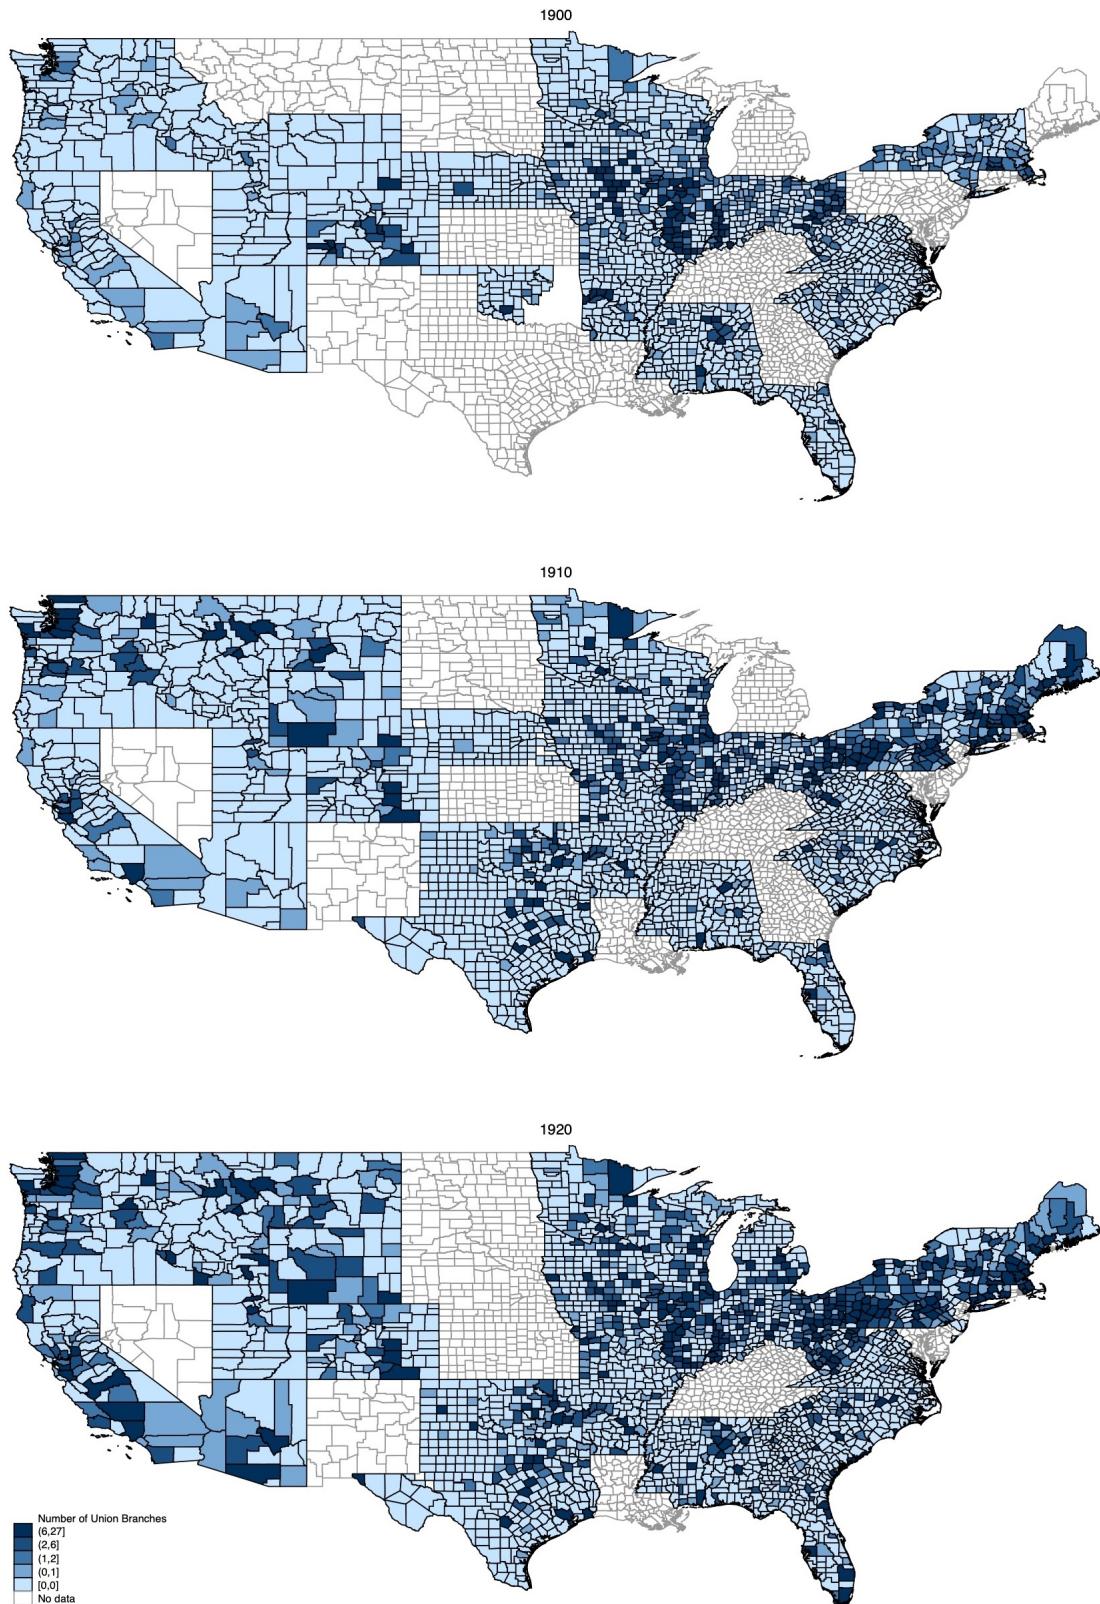

Notes: The figure shows the number of foreign-born individuals as a percent of the U.S. population, between 1850 and 2020. Source: Author's calculations from full count and samples of the U.S. Census of Population, made available by IPUMS (Ruggles et al., 2021) and ICSPR (Haines, 2010).

Figure 4: Sending Regions within the Foreign Born Population, 1850–1920

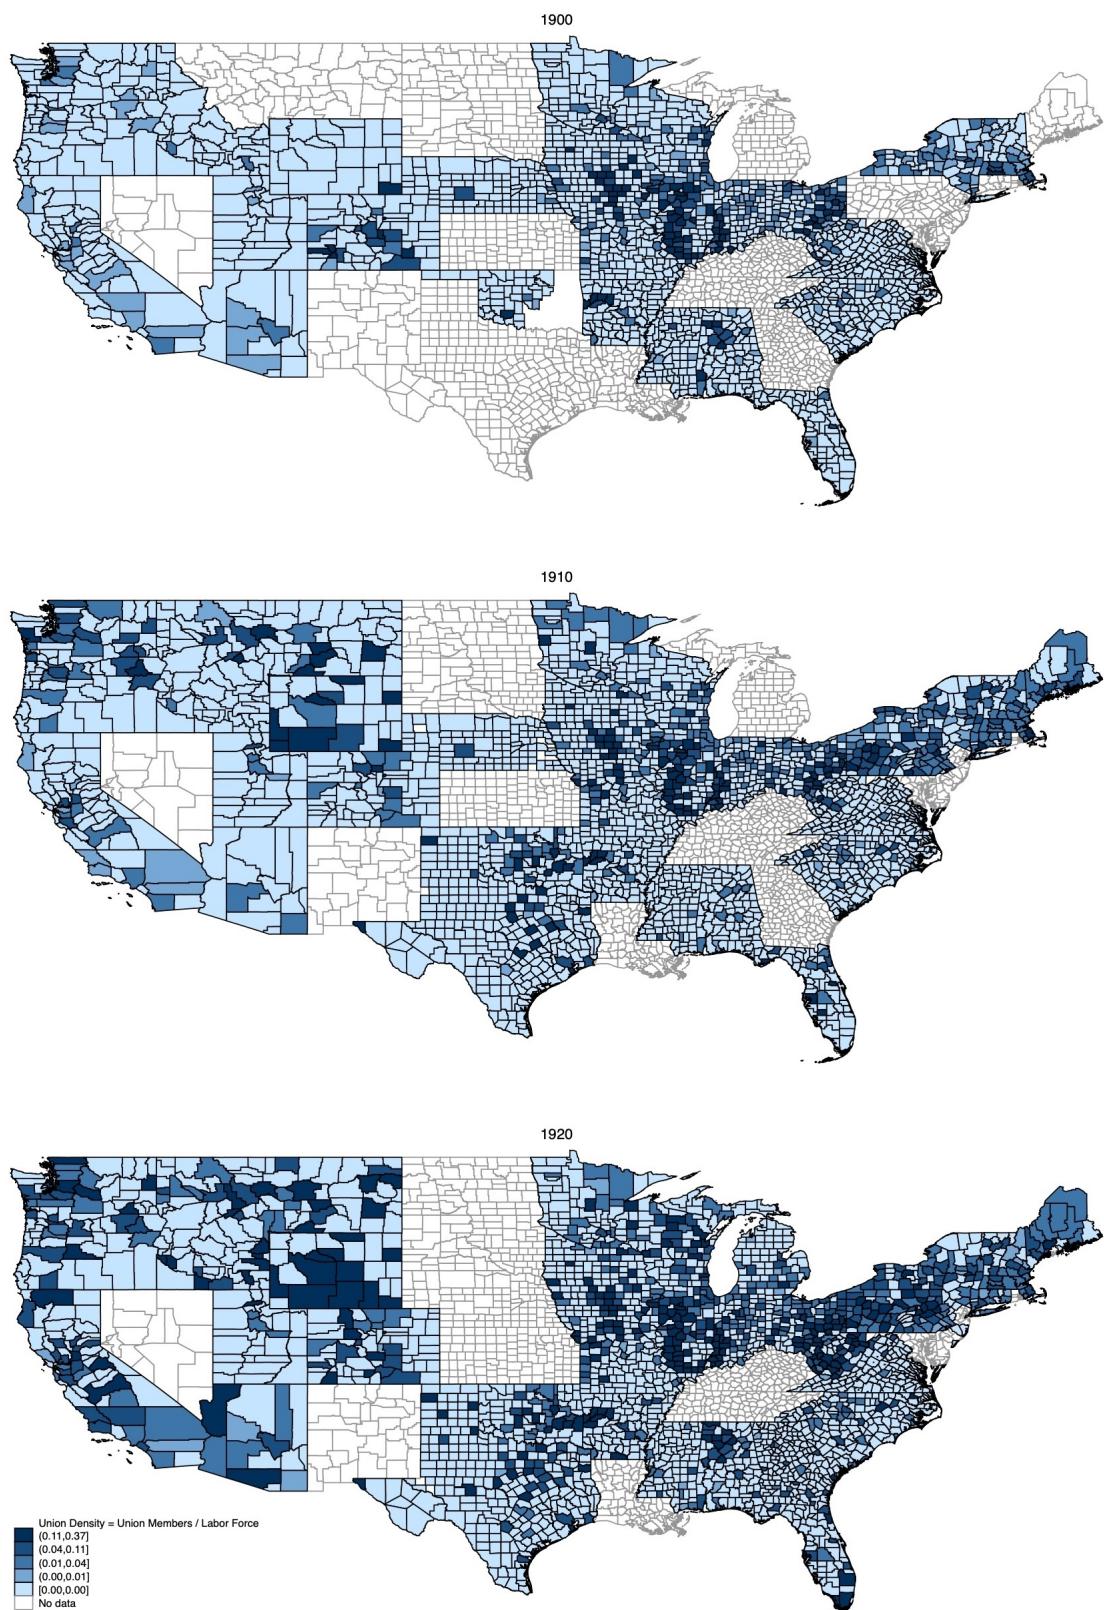

Notes: The figure shows the number of foreign-born individuals by region of origin, as a share of the total foreign-born population, between 1850 and 1920. Source: Author's calculations from full count U.S. Census of Population, made available by IPUMS (Ruggles et al., 2021) and ICSPR (Haines, 2010).

Figure 5: Geographic Distribution of Union Branches, 1900–1920

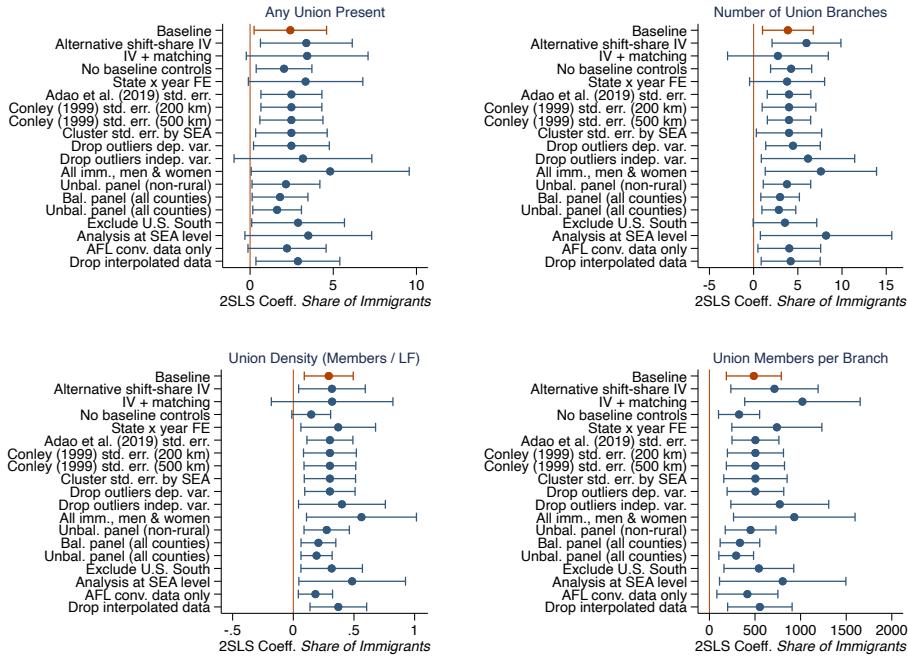

Notes: The maps plot the county-level number of union branches in 1900, 1910, and 1920. The legend shows the deciles of the distribution in 1920. Source: Author's calculations from union convention proceedings, as described in Section 3.

Figure 6: Geographic Distribution of Union Density, 1900–1920

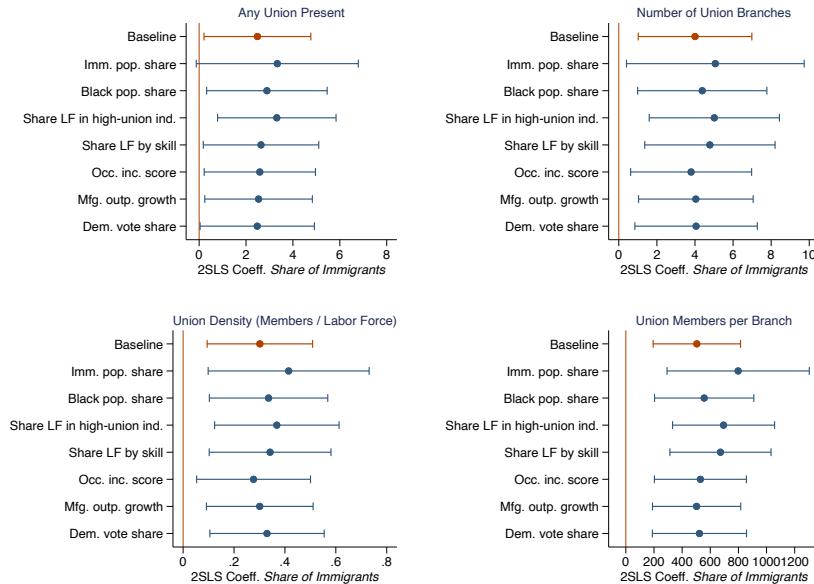

Notes: The maps plot the county-level union density (i.e., the number of union members as a fraction of the labor force, as defined in Section 3.1) in 1900, 1910, and 1920. The legend shows the deciles of the distribution in 1920. Source: Author's calculations from union convention proceedings, as described in Section 3.

Figure 7: Summary of Robustness Checks

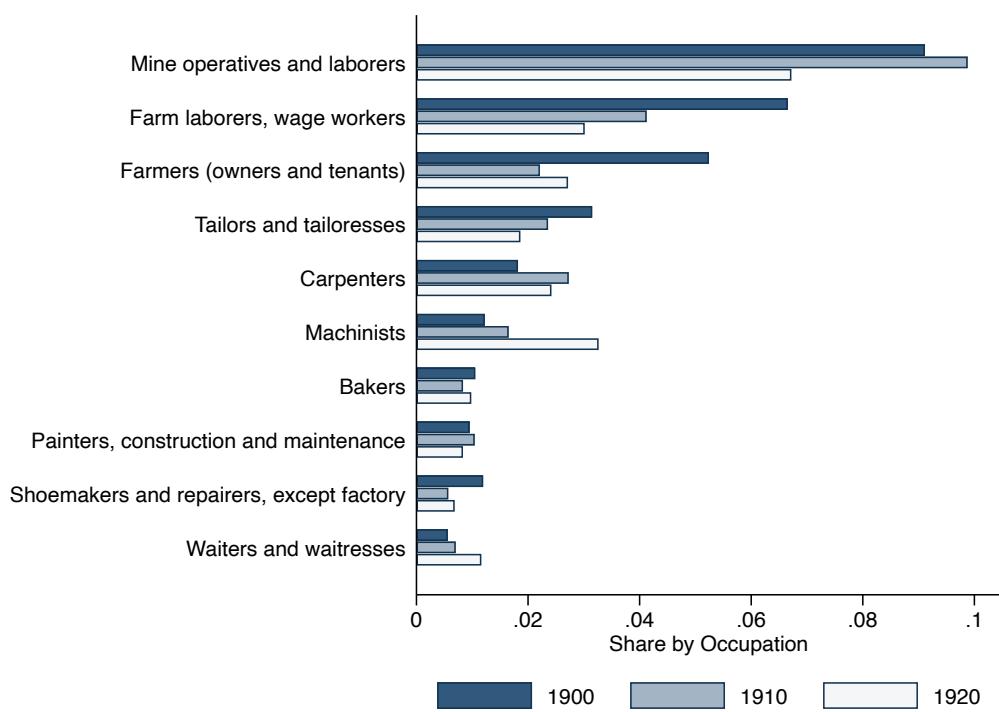

Notes: The figure presents a summary of the main robustness checks described in Section 5.3. The estimates plotted are the 2SLS coefficients (with corresponding 95% confidence intervals) of *Share of Immigrants*, the main independent variable of equation (1). The first coefficient at the top of each figure (in orange) corresponds to that from the preferred specification shown in Table 3. Standard errors are robust and clustered by county, unless indicated otherwise. For more details and formal estimates, see also Appendix B.

Figure 8: Robustness Check – Controlling for Additional Baseline Characteristics

Notes: The figure plots the 2SLS coefficients (with corresponding 95% confidence intervals) of *Share of Immigrants*, the main independent variable of equation (1), augmenting the preferred specification of Table 3 with the variable(s) indicated in each row, measured at baseline and interacted with year dummies. The first coefficient at the top of each figure (in orange) corresponds to that from the preferred specification shown in Table 3. Standard errors are robust and clustered by county. For more details, see the description of the robustness checks in Section 5.3 and the formal estimates presented in Appendix B.

Figure 9: Prevailing Occupations Among Immigrants 1900–1920

Notes: The figure shows the prevailing occupations among the European immigrants who entered the United States between 1891 and 1920. The shares indicate the number of immigrants with the reported occupation as a fraction of the total number of immigrants. Generic categories of occupations (e.g., "laborers (n.e.c.)") are not reported.

A Additional Tables and Figures

Table A.1: European Countries and Regions for Shift-Share Instrument

Austria-Hungary	Luxembourg
Belgium	Netherlands
Czechoslovakia	Norway
Denmark	Poland
France	Russia
Germany	Sweden
Greece-Portugal-Spain	Switzerland
Ireland	U.K. (England-Scotland-Wales)
Italy	

Notes: This table lists the European origin countries and regions used to construct the instrument for immigration described in Section 4.2. The stocks of foreign-born individuals by country are from the county-level data of the 1890 Census of Population (Haines, 2010).

Table A.2: Correlation Between Immigration and County Characteristics in 1890

<i>Dependent variable:</i> European Immigrant Population	
Share of Families in Farming	-2.705*** (0.404)
Share of Population in Manufacturing	15.931*** (2.139)
Number of Coal Mines per 1,000 people	0.459*** (0.099)
Presence of Railroad	1.775*** (0.257)
Observations	876

Notes: The observations are at the county level for the year 1890. The dependent variable is the log of one plus the number of European immigrants living in the county. The independent variables are the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. Robust standard errors are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table A.3: Heterogeneous Effects by Workers' Skills – Intensive Margin

	Number of Union Branches (1)	<i>Dependent variable:</i> Union Density (Members / LF) (2)	Union Members per Branch (3)
<i>Panel A: Skilled Workers</i>			
Share of Immigrants	6.707** (3.226)	1.469*** (0.525)	723.442** (308.279)
Observations	822	822	822

Observations	2,624	2,624	2,624	2,624
Dep. var. mean	0.444	2.625	0.037	48.269
Indep. var. mean (Share of Immigrants)	0.028	0.028	0.028	0.028
KP F-statistic	31.99	31.99	31.99	31.99
SW F-statistic (Share of Immigrants)	83.59	83.59	83.59	83.59
SW F-statistic (Sh. of Imm. x Sk. Comp.)	42.91	42.91	42.91	42.91
SW F-statistic (Sh. of Imm. x Unsk. Comp.)	51.16	51.16	51.16	51.16

Notes: The observations are at the county-year level. The dependent variables are: an indicator for whether the county has any labor union (column 1); the log of one plus the number of union branches (column 2); union density, defined as the number of union members divided by the total male nonfarm labor force (column 3); and the number of members per branch, or zero if the county has no union branch (column 4). The mean of the dependent variable in column (2) reflects the average number of union branches, not the log-transformed value. The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. Skilled (Unskilled) Competition is a standardized measure of immigrants' labor market competition, based on the prevailing skilled (unskilled) occupations among the U.S.-born workers in the county at the beginning of each decade and among the immigrants entering all other U.S. counties during that decade, as detailed in Section 6. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. SW F-statistic refers to the Sanderson-Windmeijer F-statistic of the instruments in the three separate first-stage regressions. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table A.7: Heterogeneous Effects by Religion in Country of Origin

	<i>Dependent variable:</i>			
	Any Union Present (1)	Number of Union Branches (2)	Union Density (Members / LF) (3)	Union Members per Branch (4)
Share of non-Protestant Immigrants	3.198 (2.035) [0.211]	5.723** (2.826) [0.198]	0.410** (0.193) [0.174]	696.735** (292.350) [0.310]

Table A.12: Effect on Local Economic Outcomes

	Dependent variable:			
	Labor Force Part. Rate (1)	Mfg. Output (per Worker) (2)	Mfg. Output (Share of U.S. Total) (3)	Labor Force in Skilled Occupations (4)
Share of Immigrants	-0.031 (0.100)	-0.667 (1.175)	-0.003 (0.015)	2.850* (1.558)
Standardized coefficient	[-0.035]	[-0.055]	[-0.033]	[0.095]
Observations	2,628	2,595	2,595	2,628
Outcome mean	0.909	3163.887	0.001	4675.349
Imm. Share mean	0.028	0.028	0.028	0.028
KP F-statistic	65.27	64.58	64.58	65.27

Notes: The observations are at the county-year level. The dependent variables are: the male labor force participation rate (column 1); the log of the manufacturing output divided by the manufacturing labor force (column 2); the manufacturing output as a share of the total manufacturing output in the United States in that year (column 3); and the log of the total male labor force in skilled occupations (column 4). The value of manufacturing output for the year 1910, which would otherwise be missing, is linearly interpolated. The dependent variables in columns (2) and (3) are expressed in 2020 USD. The main regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Square brackets report standardized coefficients. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table A.13: Changes to U.S.-Born Workers' Occupations

	Dependent variable:					
	Share of U.S.-Born LF in AFL-Covered Occupations			Without local union branch		
	With local union branch			All (4)	Skilled (5)	Unskilled (6)
	All (1)	Skilled (2)	Unskilled (3)			
Share Immigrants	0.929** (0.446)	0.163** (0.082)	0.044 (0.035)	-0.824** (0.379)	-0.038 (0.082)	-0.063* (0.033)
Observations	2,628	2,628	2,628	2,628	2,628	2,628
Dep. var. mean	0.150	0.021	0.007	0.109	0.076	0.021
Indep. var. mean	0.028	0.028	0.028	0.028	0.028	0.028
KP F-statistic	65.27	65.27	65.27	65.27	65.27	65.27

Notes: The observations are at the county-year level. The dependent variables are: the shares of U.S.-born workers (men ages 16–64) in the labor force who are in occupations that have positive union membership in the county (columns 1–3) or no union representation in the county (columns 4–6). All (columns 1 and 4) refers to all occupations covered by an AFL-affiliated national union; Skilled (columns 2 and 5) refers to the occupations covered by the ten largest AFL-affiliated national unions that represented skilled workers; Unskilled (columns 3 and 6) refers to the AFL-affiliated national unions that represented unskilled workers. The main regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table A.14: Effect on U.S.-Born Workers' Labor Market Outcomes

	<i>Dependent variable:</i>	
	Labor Force Participation Rate (1)	Occupational Income Score (2)
Share of Immigrants	-0.011 (0.109)	0.219 (0.181)
Observations	2,628	2,628
Dep. var. mean	0.903	20.412
Indep. var. mean	0.028	0.028
KP F-statistic	65.27	65.27

Notes: The observations are at the county-year level. The dependent variables are the labor force participation rate among U.S.-born workers, men ages 16–64 (column 1), and the log of the average occupational income score among U.S.-born workers (column 2). The main regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table A.15: Persistent Effect of Immigration on Unionization

	<i>Dependent variable:</i>		
	Union Density in Private Sector (avg. 2000–2020)		
	Total (1)	Construction (2)	Manufacturing (3)
Share of Immigrants (avg. 1900–1920)	0.724*** (0.123)	1.878*** (0.354)	0.269 (0.265)
Observations	163	163	163
Dep. var. mean	0.066	0.157	0.102
Indep. var. mean	0.036	0.036	0.036
KP F-statistic	67.62	67.62	67.62

Notes: The observations are at the metropolitan area (MSA) level. The dependent variables are the average union density between 2000 and 2020 in: the whole private sector (column 1), the private construction sector (column 2), and the private manufacturing sector (column 3). The main regressor of interest is the 1900–1920 average number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the metropolitan area. The instrument used to predict it is the average between 1900 and 1920 of the one described in Section 4.2, after aggregating the data at the metropolitan area level. All regressions include the following controls, measured in 1890: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the metropolitan area. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Robust standard errors are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table A.16: Unionization and Wage Inequality

	<i>Dependent variable: Wage Inequality</i>		
	90/10 (1)	90/50 (2)	50/10 (3)
<i>Panel A</i>			
Any Union Present	-0.123*** (0.024)	-0.095*** (0.014)	-0.028 (0.018)
Observations	871	871	871
Dep. var. mean	1.813	0.789	1.023
Indep. var. mean	0.529	0.529	0.529
<i>Panel B</i>			
Union Density (Members / LF)	-0.238** (0.121)	-0.271*** (0.074)	0.033 (0.095)
Observations	871	871	871
Dep. var. mean	1.813	0.789	1.023
Indep. var. mean	0.054	0.054	0.054

Notes: The observations are at the county level. The dependent variables are measures of wage inequality in 1940, proxied by log wage differentials for full-time, full-year workers computed at the following percentiles: 90 to 10 (column 1); 90 to 50 (column 2); or, 50 to 10 (column 3). The main regressors of interest are an indicator for whether the county has any labor union in 1920 (Panel A) or union density (number of union members divided by the total male nonfarm labor force) in 1920 (Panel B). All regressions include the following controls, measured in 1890: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. Robust standard errors are shown in parentheses.

*** p<0.01; ** p<0.05; * p<0.1.

Table A.17: Effect on the Composition of Union Leaders

	Dependent variable: Share of Union Leaders					
	U.S. (1)	N/W Europe (2)	S/E Europe (3)	U.S. (4)	N/W Europe (5)	S/E Europe (6)
All counties			Always unionized counties			
<i>Panel A: Origin country</i>						
Share of Immigrants	2.339** (1.053)	0.534 (0.369)	0.065 (0.133)	0.141 (0.280)	-0.136 (0.234)	0.038 (0.175)
Dep. var. mean	0.343	0.031	0.009	0.870	0.089	0.024
<i>Panel B: Ancestry</i>						
Share of Immigrants		2.521** (1.148)	0.505 (0.373)		0.029 (0.394)	0.108 (0.384)
Dep. var. mean		0.344	0.038		0.881	0.101
Observations	2,628	2,628	2,628	582	582	582
Indep. var. mean	0.028	0.028	0.028	0.046	0.046	0.046
KP F-statistic	65.27	65.27	65.27	13.76	13.76	13.76

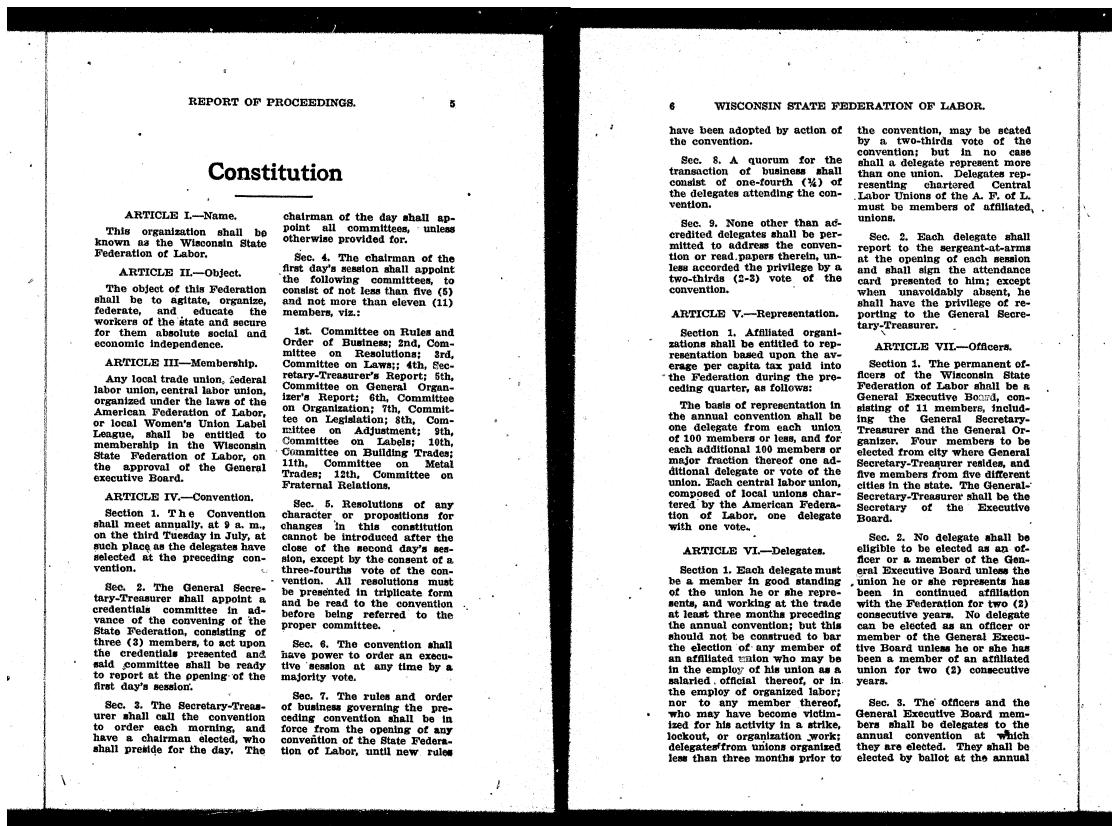

Notes: The observations are at the county-year level. The dependent variable is the share of union delegates whose last name is of the origin (Panel A) or ancestry (Panel B) indicated in the column headings. The procedure used to infer the origin and the ancestry from last names is described in Section C. The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. In columns 1 to 3, the sample includes all counties as in Table 3 (in counties with no unionization, both the shares of U.S.-born and of European delegates are set to zero); in columns 4 to 6, the sample is restricted only to counties for which a union delegate is observed in every year. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Notes: The figure shows a digitized document from the proceedings of the state federations of labor's conventions. The documents contain information on the number of branches represented at the conventions, along with information on their delegates.

Figure A.2: Example of Digitized Document on Representation Rules at Conventions

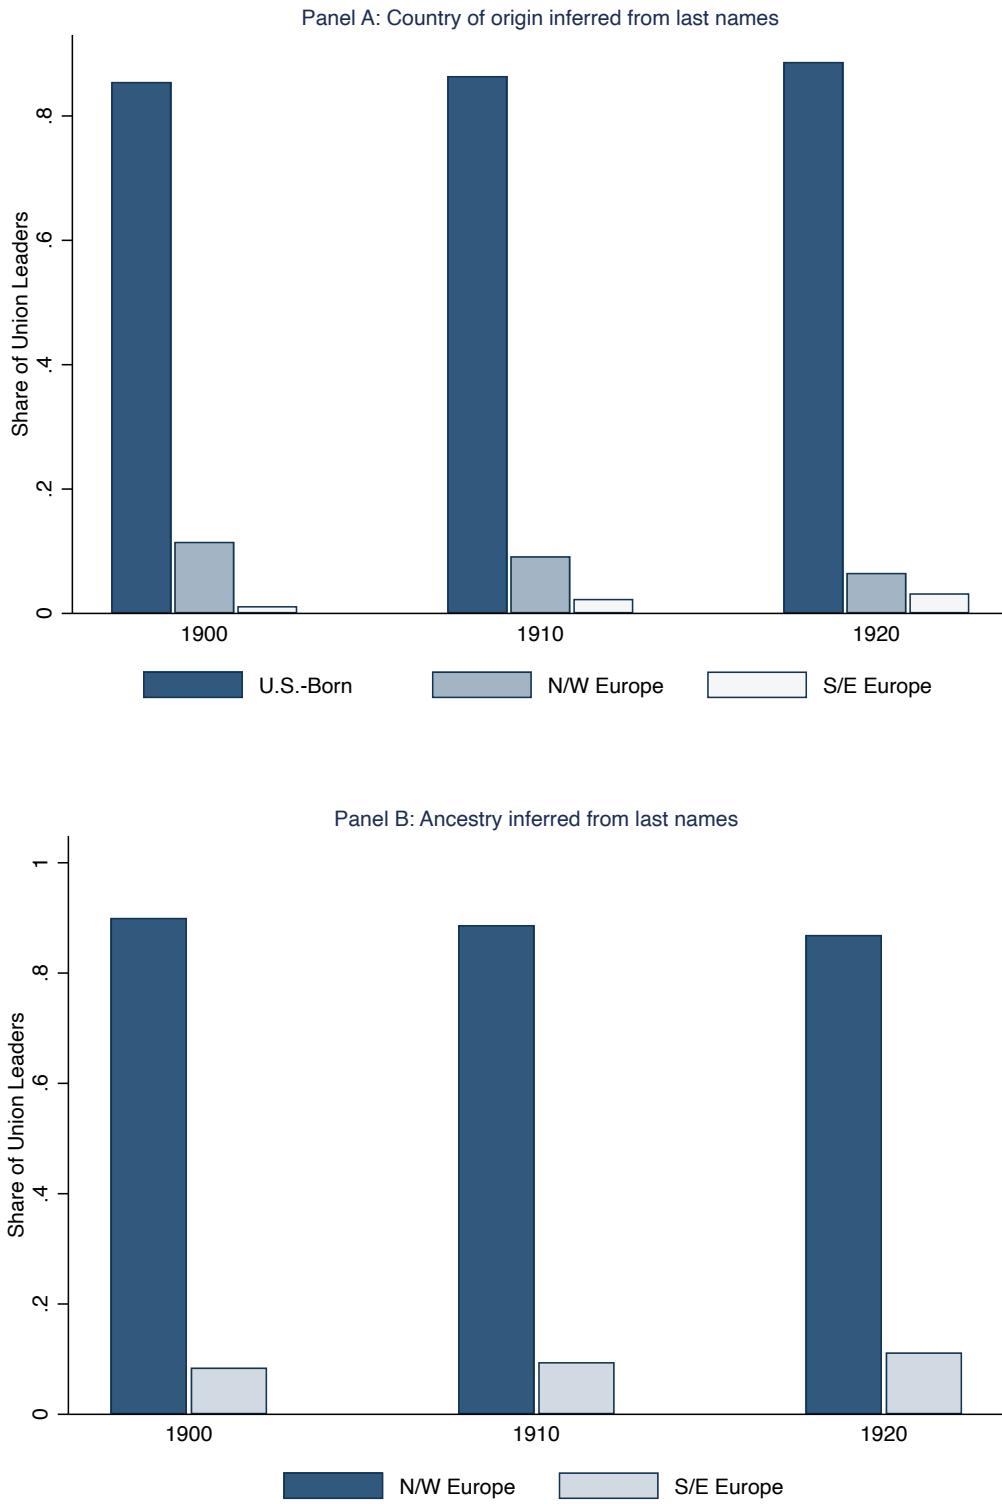

Notes: The figure shows a digitized document from the constitutions of the state federations of labor. The documents contain information on the rules that establish the number of delegates that local branches could send to the conventions. The highlighted paragraph on the page on the right provides an example.

Figure A.3: Correlation Between Measures Across Data Sources

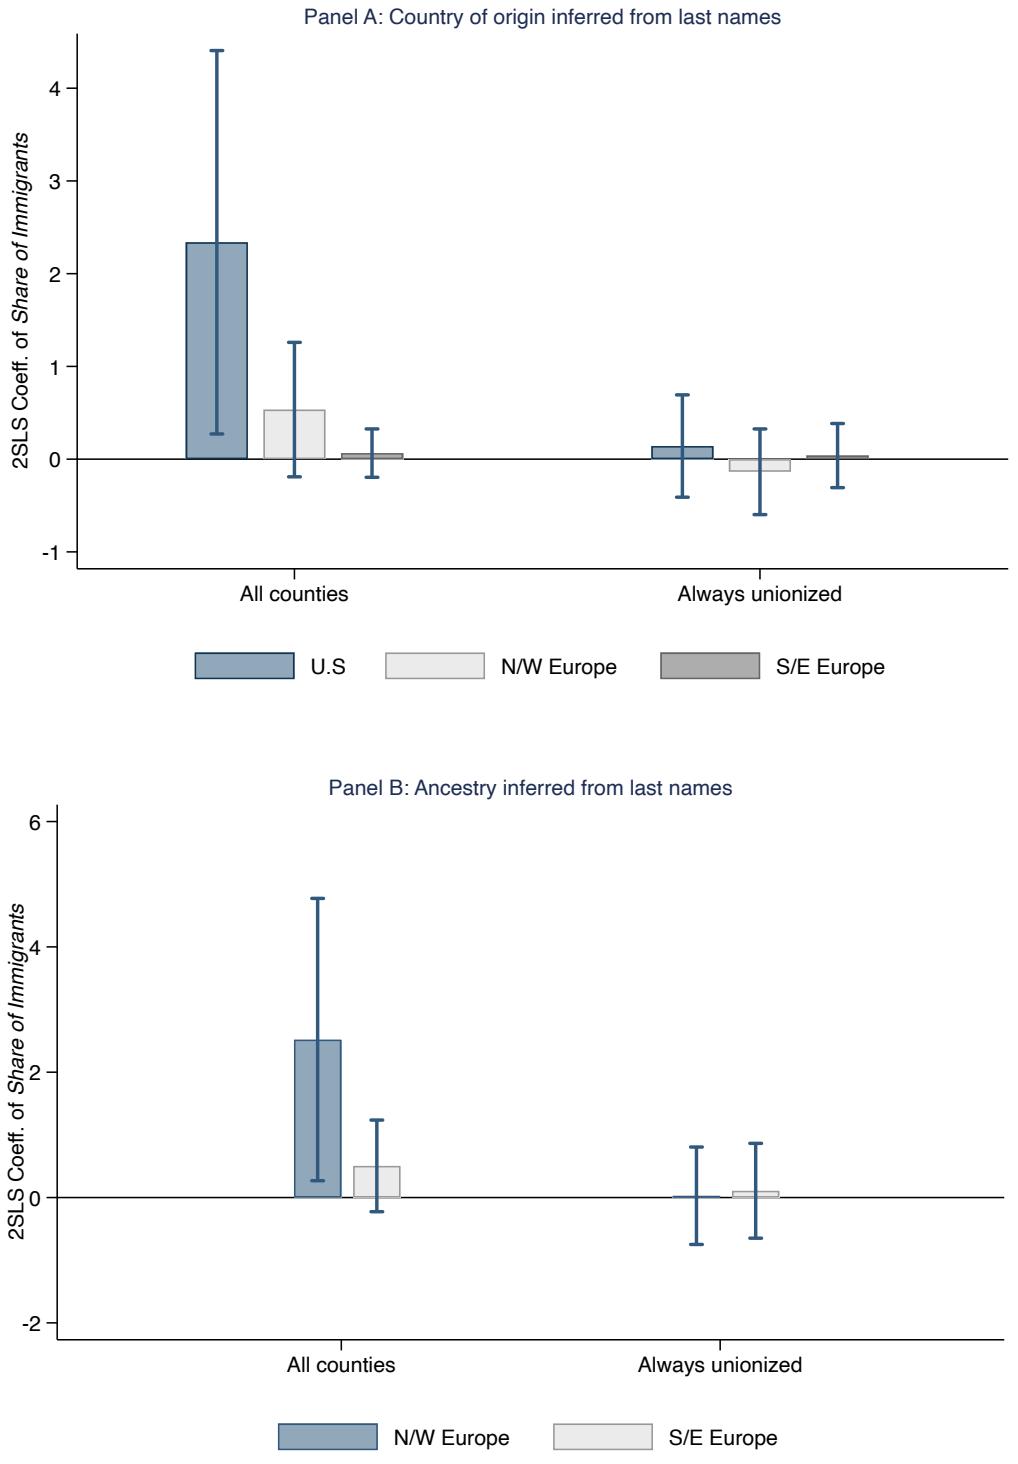

Notes: The figure shows binned scatter plots of the county-level union membership estimates (Panel A) and number of union branches (Panel B), constructed using the main data source (convention proceedings of the state federations of labor, on the x-axis) and the complementary data source (convention proceedings of the AFL-affiliated national unions, on the y-axis). Each graph shows the correlation between the two measures for each of the six national unions that are observed in both sources. See Section 3 for more details.

Figure A.4: Shares of Union Leaders by Origin and Ancestry

Notes: The figure plots the shares of union leaders of U.S.-born, Northern/Western Europe, and Southern/Eastern Europe origin (Panel A) and of Northern/Western and Southern/Eastern Europe ancestry (Panel B), at the beginning of each decade between 1900 and 1920. Union leaders are the delegates sent by the local union branches to the national convention of their union, or to the state conventions of the American Federation of Labor. The country of origin and the ancestry are inferred from delegates' last names, as described in Appendix C.

Figure A.5: Effect on the Composition of Union Leaders

Notes: Bars plot coefficients (with corresponding 95% confidence intervals) of a 2SLS regression of the share of union leaders with inferred country of origin (U.S., N/W Europe, S/E Europe, in Panel A) or ancestry (N/W and S/E Europe, Panel B) on the share of recently arrived immigrants. Union leaders are the delegates sent by the local union branches to the national convention of their union, or to the state conventions of the American Federation of Labor. On the left, the sample includes all counties as in Table 3 (in counties with no unionization, both shares are set to zero); on the right, the sample is restricted only to counties for which a union delegate is observed in every year. The country of origin and the ancestry are inferred from delegates' last names, as described in Appendix C. Formal estimates are presented in Table A.17.

B Robustness Checks

B.1 Alternative Shift-Share Instrument

As explained in Section 4.2, I replicate the analysis using an alternative instrument that relies on *predicted* flows of European immigration. More specifically, in equation (2), I replace the actual number of immigrants from country j entering the U.S. between year $t - 10$ and year t , with that predicted exploiting variation in weather shocks across European countries over time. This is motivated by previous work which has documented links between agricultural output and weather conditions, both in Europe during the Age of Mass Migration (Hatton and Williamson, 1995; Solomou and Wu, 1999) and in contemporary migration episodes (Feng et al., 2010).

I follow Sequeira et al. (2020),⁵⁴ and estimate a relationship between weather shocks and immigration from each European country (for the period 1900–1920) using the following equation:

$$\log(Immigr_{j,t}) = \sum_{s \in S} \sum_{k \in K} \beta_{j,s,k} I_{j,t-1}^{s,k} + u_{j,t} \quad (\text{B.1})$$

where $\log(Immigr_{j,t})$ is the log of immigrants from European country j in year t ; and $I_{j,t-1}^{s,k}$ is a dummy equal to 1 if the average precipitation (or temperature) in season $s \in \{\text{Spring, Summer, Fall, Winter}\}$ falls in the range k . As in Sequeira et al. (2020), k indexes a set of six weather shock categories: more than 3 standard deviations below the mean; between 2 and 3 standard deviations below the mean; between 1 and 2 standard deviations below the mean; between 1 and 2 standard deviations above the mean; between 2 and 3 standard deviations above the mean; and more than 3 standard deviations above the mean. The omitted category is the one of temperatures (or precipitations) that are within one standard deviation below or above the mean. Since there are six temperature categories and four seasons, there are 24 weather indicators in total.

The data on historical temperatures and precipitations come from Luterbacher et al. (2004) and Pauling et al. (2006), respectively. The data are measured four times annually (once during each season) and approximately at a 55-kilometer spatial resolution. Because the immigration data (from Willcox, 1929) are at the country-level, I average temperatures and precipitations over all grid-cells under cultivation in a country.⁵⁵ For this exercise, the sample includes nineteen European countries for which immigration, weather, and crop data are available.⁵⁶ In the baseline specification, I consider temperature shocks, but results are unchanged if using precipitations.

⁵⁴An analogous identification is also used by Tabellini (2020).

⁵⁵Information on historical land under cultivation is from Ramankutty and Foley (1999).

⁵⁶These are: Austria, Belgium, Denmark, England, France, Germany, Greece, Hungary, Ireland, Italy, the Netherlands, Norway, Portugal, Russia, Scotland, Spain, Sweden, Switzerland, and Wales.

I separately estimate equation (B.1) for each European country in the sample. Figure B.1 shows the relationship between actual and predicted log immigration, displaying a strong positive correlation. Then, I predict the log immigrant flows for each country in each year, $\log(\widehat{Immigr}_{j,t})$ using the $\widehat{\beta}_{j,s,k}$'s estimated from these regressions. Finally, I aggregate the predicted flows by decade and obtain:

$$\widehat{O}_{jt} = \sum_t \exp[\log(\widehat{Immigr}_{j,t})] \quad (\text{B.2})$$

Table B.1 reports the first stage estimates. Although the F-stat is lower than the one of the main instrument (Table 2), it is still always above the conventional levels. Table B.2 shows the main results on the effect of immigration on the four unionization measures. Panel A reports the baseline estimates of Table 3 using the main instrument, while Panel B displays the estimates with the alternative instrument based on weather shocks. In either case, all coefficients are positive and statistically significant at the 1% or 5% level.

B.2 Matching Exercise

Similar to Bazzi et al. (2023), I combine the main empirical strategy based on a shift-share instrumental variable with a matching exercise. I identify county pairs within the same state that have the closest number of Knights of Labor branches as a fraction of the county population, in 1880 and in 1890. In the absence of comprehensive information on unions affiliated with the American Federation of Labor before 1890 (the AFL was only established in 1886), or of complete data on the union membership of the Knights of Labor, this is one way to measure unionization at the county level before the time period analyzed in the paper.

I present the results in Table B.3. In Panel A, I re-estimate the baseline specification of Table 3 for the counties that can be included in the county-pair strategy.⁵⁷ In Panels B and C, I re-estimate equation (1), replacing the baseline controls with fixed effects for the county pairs, interacted with year dummies. In Panel B, counties are matched on the number of Knights of Labor branches per capita in 1880. In Panel C, on the one of 1890. The resulting coefficients identify the effect of immigration inflows on unionization for counties with nearly identical levels of union presence at baseline.⁵⁸ Despite the very de-

⁵⁷Not all counties can be matched in pairs (e.g., when there is an odd number of counties in a state). For this reason, the number of observations for the matching exercise is slightly lower than in the main estimation sample.

⁵⁸In case of equal values of the matching variable, I further match counties on these additional variables, in the following order: total number of Knights of Labor branches in the county, share of population in manufacturing, share of population in farming, share of population in mining (for the year 1880; for the year 1890, due to data availability, this variable is replaced by the number of coal mines per population), and an indicator for the presence of a railroad in the county. This is meant to compare counties that have similar economic conditions at baseline. Further ties are then broken arbitrarily by a randomly generated number. Different choices of the "secondary" matching variables do not affect the results.

manding nature of this specification, reassuringly all the point estimates remain positive, in some cases are precisely estimated, and are similar to the baseline coefficients of Panel A.

B.3 Controlling for Additional Baseline Characteristics

In this section, I address the possibility that the instrument described in Section 4.2 may predict a higher immigrant share in counties that were already on a trajectory of higher unionization growth, for either economic or political reasons. In Table B.4, I augment the preferred specification by interacting several characteristics measured at baseline with year dummies. This exercise is meant to reduce the concern that factors jointly correlated with the 1890 size of immigration and the development of labor unions between 1900 and 1920 may bias the estimates. The coefficients reported in column 1 are repeated from Table 3 for comparison.

Share of immigrant population. I directly control for the size of the 1890 total immigrant population, interacted with year dummies. This implies that the effects of immigration are identified exploiting variation only in the ethnic composition of immigrant enclaves across counties, holding constant the size of their foreign born populations. Since mechanically the instrument predicts higher immigration to counties with a larger stock of immigrants at baseline, by doing this I also address the concern that a larger 1890 immigrant population may itself have an independent and time-varying effect on unionization. Despite the highly demanding nature of this specification, all estimates remain statistically significant above the conventional levels (column 2).

Share of Black population. Another potential confounding factor may be represented by the first waves of the Great Migration, which started around 1915 (Boustan, 2016). Although a limited cause of concern given the little overlap with the period studied, I address this possibility by controlling for the shares of Black population in each county in 1890, which will higher immigration rates of Black individuals based on chain migration, as previous work has shown (Boustan, 2010; Fouka et al., 2022). The findings are unchanged (column 3).

Labor force composition. I further control for the shares of the labor force in 1890 in (i) the industries with the largest AFL-affiliated labor unions during the period 1900–1920: mining, construction, and transportation (Stewart, 1926); (ii) and by skill level: low-skilled, mid-skilled, and high-skilled (Katz and Margo, 2014). These regressions therefore estimate the effect of immigration among counties with similar initial size of the labor force in sectors and skills conducive to unionization. The results are all positive and statistically significant, and larger in magnitude (columns 4 and 5).

Average income and economic growth. Similarly, I control for the initial levels of average income (proxied by the occupational income score) and economic growth (measured

by the growth rate of manufacturing output), to reduce any concern that counties with different economic conditions may have attracted more immigration earlier on and also witnessed a different growth of labor unions over time. The estimates are robust to the inclusion of these additional controls (columns 6 and 7).

Share of land in farms. An additional concern is represented by the structural transformation away from agriculture towards manufacturing that occurred in the U.S. between 1880 and 1920 ([Eckert and Peters, 2022](#)). This may have implied larger growth rates for counties that were more rural at the beginning of the time period, with potential implications on the evolution of labor unions too. Although in the baseline specification I already control for the share of the population in farming in 1890, I further include interactions between year dummies and the 1890 share of land in farms. The results are almost unchanged (column 8).

Vote shares for the Democratic Party. Finally, I control for a measure of the political ideology of each county, namely the average vote shares for the Democratic Party in the presidential elections of 1888 and 1892. Also in this case, all the point estimates are remarkably similar to the baseline estimates (column 9).

B.4 Additional Robustness Checks

Alternative baseline specification. Table [B.5](#) reports results from using different specifications. In particular, in columns 1 to 5 I estimate less stringent specifications, by gradually including the controls, measured in 1890 and interacted with year dummies, that are part of the preferred specification: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. In columns 6 to 10, I do the same, while also always including state by year fixed effects, implying that the coefficients are estimated from changes in the fraction of immigrants within the same county over time, compared to other counties in the same state in a given year. The estimates are quantitatively and qualitatively unchanged.

Alternative standard errors. All the results in the paper report standard errors clustered at the county level. In Table [B.6](#), I report standard errors using four alternative procedures: the adjustment proposed by [Adao et al. \(2019\)](#) for shift-share instrumental variables, the approach of [Conley \(1999\)](#) to account for spatial correlation (using a 200km- or 500km-bandwidth), and clustering by State Economic Area, i.e., single counties or groups of contiguous counties within the same state identified by the Census Bureau as having similar economic characteristics ([Bogue, 1951](#)). All coefficients are statistically significant at the 1% level.

Drop potential outliers. I verify that the results are robust to omitting observations with very large and very low levels of the dependent and independent variables, which could

be potential outliers. In Table B.7, I re-estimate the baseline results dropping observations with measures of unionization (Panel A) and immigration (Panel B) below the 1st and above the 99th percentile. Reassuringly, in all cases the coefficients are in line with those reported in Table 3.

Alternative definitions of *Share of Immigrants*. As described in Section 4, the definition of *Share of Immigrants* used in the paper is the number of male working-age (16-64 years old) European immigrants who entered the United States in the previous ten years as a fraction of the male working-age population. In Table B.8, I show that the results are robust when using alternative definitions of the main independent variable. In Table A, *Share of Immigrants* is defined as the total number of the male working-age European immigrant population, regardless of when they arrived to the United States, as a fraction of the male working age population. In Panel B, it is the number of all (men and women) recently entered (within the previous 10 years) working-age European immigrants as a fraction of the total working-age population. In Panel C, it is the number of all working-age European immigrants as a fraction of the total working-age population. In Panel D, the independent variable is the total number of European immigrants as a fraction of the total population. In all four panels, the coefficients are positive and statistically significant for all four unionization measures.

Alternative definitions of *Union Density*. The preferred definition of union density used throughout the paper is the number of union members as a fraction of the total male labor force, except farmers and farm laborers, managers and proprietors, and those working in private household service. In Table B.9, I show that the results are unchanged when using different definitions of this unionization measure. In column 1, the number of union members is divided by the total male labor force, except farmers and farm laborers. In column 2, the denominator is the total male labor force. In column 3, it is the total labor force. As expected, the size of the coefficient decreases as the denominator increases from column 1 to column 3, but all three estimates are statistically significant at the 1% or 5% level.

Alternative samples. In Table B.10, I re-estimate the preferred specification of Table 3 using alternative samples. In Panel A to C, I ensure that the results are not specific to the balanced panel of urban and mining counties (i.e., counties with a positive urban population or at least one coal mine in 1890) used throughout the paper. More specifically, in Panel A, the sample is a balanced panel of both urban and rural counties. In Panel B, the sample is an unbalanced panel of only urban or mining counties. In Panel C, the sample is composed of all county-year observations for which the unionization data are available. Finally, in Panel D, the counties in the South are excluded from the preferred estimation sample of Table 3. This exercise is motivated by the fact that this region of the United States received low levels of immigration between 1890 and 1920, and also experienced limited organized labor activity. Hence, a possible concern is that Southern

counties may be driving the positive relationship between immigration and unionization. Across all panels, the coefficients are positive and statistically significant.

Analysis at the SEA level. In Table B.11, I re-estimate the main results from Table 3 using data aggregated at the State Economic Area (SEA) level, a reasonable proxy for integrated labor markets at the time (similar to today's commuting zones). Despite the lower number of observations and consequently a lower F-statistic, the effects of immigration on all four measures of unionization remain positive and statistically significant at the 5% or 10% level.

Alternative data construction. In Section 3.1, I described the steps followed to construct the novel dataset on county-level unionization used in this paper. In Table B.12, I ensure that the results are not driven by any interpolated value of unionization (in Panel A I omit such observations; in Panel B I control for an indicator equal to one if the observation is interpolated). In Table B.13, I re-estimate the analysis only relying on the convention proceedings of the state federations of labor (without combining them with the proceedings from some of the largest AFL-affiliated national unions). In both tables, the results are very similar to those reported in Table 3 and always statistically significant.

Test of pre-trends. The validity of the shift-share instrument defined by equation (2) rests on the key assumption that counties receiving more immigrants (from each country) before 1890 must not be on different trajectories for the evolution of unionization in subsequent decades (see also Borusyak et al., 2022 and Goldsmith-Pinkham et al., 2020). Although the results of Figure 8 already reduce the concerns about this assumption being invalidated, in Table B.14, I test for pre-trends more directly, regressing the pre-period change (between 1880 and 1890) of measures of unionization, population, and economic growth, on the 1900 to 1920 average immigration flows predicted by the instrument. Similarly to the preferred specification used in the rest of the paper, all regressions include the following county controls, measured in 1880: the share of population in farming, the share of population in manufacturing, the share of population in mining, and an indicator for the presence of a railroad in the county.⁵⁹ The choice of the dependent variables is constrained by data availability. Given the absence of local data on union membership before the sample period analyzed in the paper, and the fact that the American Federation of Labor was constituted only in 1886, I measure unionization with an indicator for the presence of any branch of the Knights of Labor (column 1); for population and economic measures, I examine the share of urban population (column 2) and three measures of from the Census of Manufacturing: the number of establishments (column 3), the value of manufacturing output (column 4), and the value of output per manufacturing worker (column 5).⁶⁰ Reassuringly, no coefficient of Table B.14 is statistically significant.

⁵⁹For the analysis reported in this table I include controls measured in 1880. The same variables measured in 1890 would constitute *bad controls* (Angrist and Pischke, 2009), since the dependent variables are changes between 1880 and 1890.

⁶⁰The dependent variables in columns 3 to 5 are log-transformed after adding one to their value to allow

These results indicate that, before 1890, European immigrants did not settle in counties that were already undergoing changes in union presence or in other economic variables.

for zeroes.

Table B.1: First Stage of the Alternative Instrumental Variable Estimation

	Dependent variable: Share of Immigrants				
	(1)	(2)	(3)	(4)	(5)
Predicted Share of Immigrants	0.211*** (0.042)	0.167*** (0.035)	0.166*** (0.035)	0.166*** (0.035)	0.164*** (0.035)
Observations	2,628	2,628	2,628	2,628	2,628
Dep. var. mean	0.028	0.028	0.028	0.028	0.028
Indep. var. mean	0.094	0.094	0.094	0.094	0.094
KP F-statistic	25.30	23.27	23.12	23.07	22.47
Share of Farming in 1890	No	Yes	Yes	Yes	Yes
Share of Manufacturing in 1890	No	No	Yes	Yes	Yes
Number of Coal Mines (per 1,000 ppl.) in 1890	No	No	No	Yes	Yes
Presence of Railroad in 1890	No	No	No	No	Yes

Notes: The observations are at the county-year level. The table reports the first stage of the alternative instrument described in Appendix B.1. The dependent variable is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The main regressor of interest is the predicted number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the 1890 male population in the county. All regressions include county and year fixed effects. The following controls, measured in 1890 and interacted with year dummies, are also included: the share of families in farming (from column 2); the share of population in manufacturing (from column 3), the number of coal mines per 1,000 people (from column 4), and an indicator for the presence of a railroad in the county (column 5). KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table B.2: Alternative Shift-Share Instrument Using Predicted Immigration Flows

	<i>Dependent variable:</i>			
	Any Union Present (1)	Number of Union Branches (2)	Union Density (Members / LF) (3)	Union Members per Branch (4)
<i>Panel A: Main instrument</i>				
Share of Immigrants	2.485** (1.160)	4.004*** (1.520)	0.302*** (0.106)	504.600*** (158.205)
KP F-statistic	65.27	65.27	65.27	65.27
<i>Panel B: Alternative instrument</i>				
Share of Immigrants	3.382** (1.406)	5.982*** (1.985)	0.318** (0.140)	713.443*** (243.713)
KP F-statistic	22.47	22.47	22.47	22.47
Observations	2,628	2,628	2,628	2,628
Dep. var. mean	0.444	2.621	0.037	48.258
Indep. var. mean	0.028	0.028	0.028	0.028

Notes: The observations are at the county-year level. The dependent variables are: an indicator for whether the county has any labor union (column 1); the log of one plus the number of union branches (column 2); union density, defined as the number of union members divided by the total male nonfarm labor force (column 3); and the number of members per branch, or zero if the county has no union branch (column 4). The mean of the dependent variable in column (2) reflects the average number of union branches, not the log-transformed value. The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. In Panel A, the instrument used to predict immigration is the one described in Section 4.2. In Panel B, the instrument is the one that uses predicted rather than actual immigration flows (predicted using weather shocks in each European country, following Sequeira et al., 2020), as described in Appendix B.1. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table B.3: Matching Counties with Similar Union Presence at Baseline

	<i>Dependent variable:</i>			
	Any Union Present (1)	Number of Union Branches (2)	Union Density (Members / LF) (3)	Union Members per Branch (4)
<i>Panel A: Baseline (matching sample)</i>

Observations	2,628	2,628	2,628
Dep. var. mean	0.033	0.022	0.018
Indep. var. mean	0.028	0.028	0.028
KP F-statistic	65.27	65.27	65.27

Notes: The observations are at the county-year level. The dependent variables consist of three alternative definitions of union density, different from the one used in the rest of the paper (i.e., the number of union members as a fraction of the total male labor force, except farmers and farm laborers, managers and proprietors, and those working in private household services): the number of union members divided by the total male labor force, except farmers and farm laborers (column 1); the number of union members divided by the total male labor force (column 2); and the number of union members divided by the total (male and female) labor force (column 3). The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table B.10: Alternative Samples

	Any Union Present (1)	Number of Union Branches (2)	Dependent variable: Union Density (Members / LF) (3)	Union Members per Branch (4)
<i>Panel A: Balanced panel, urban and rural counties</i>				
Share of Immigrants	1.802** (0.854)	2.994*** (1.112)	0.207*** (0.073)	334.839*** (110.745)
Observations	4,958	4,958	4,958	4,958
KP F-statistic	30.44	30.44	30.44	30.44
<i>Panel B: Unbalanced panel, urban counties</i>				
Share of Immigrants	2.156** (1.040)	3.774*** (1.367)	0.275*** (0.095)	451.407*** (141.688)
Observations	2,908	2,908	2,908	2,908
KP F-statistic	75.17	75.17	75.17	75.17
<i>Panel C: Unbalanced panel, urban and rural counties</i>				
Share of Immigrants	1.626** (0.745)	2.852*** (0.976)	0.191** (0.066)	293.597*** (97.005)
Observations	5,738	5,738	5,738	5,738
KP F-statistic	38.25	38.25	38.25	38.25
<i>Panel D: Excluding the South</i>				
Share of Immigrants	2.886** (1.420)	3.545* (1.832)	0.316** (0.129)	542.295*** (194.945)
Observations	1,953	1,953	1,953	1,953
KP F-statistic	53.33	53.33	53.33	53.33

Notes: The observations are at the county-year level. In Panel A, the sample is restricted to a balanced panel of both urban and rural counties; in Panel B, to an unbalanced panel of urban counties, i.e., with a non-zero urban population in 1890; in Panel C, to an unbalanced panel of both urban and rural counties; and in Panel D the states in the South are excluded from the sample. The dependent variables are: an indicator for whether the county has any labor union (column 1); the log of one plus the number of union branches (column 2); union density, defined as the number of union members divided by the total male nonfarm labor force (column 3); and the number of members per branch, or zero if the county has no union branch (column 4). The mean of the dependent variable in column (2) reflects the average number of union branches, not the log-transformed value. The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table B.11: Analysis at the State Economic Area (SEA) Level

		Dependent variable:		
	Any Union Present (1)	Number of Union Branches (2)	Union Density (Members / LF) (3)	Union Members per Branch (4)
Share of Immigrants	3.500* (1.935)	8.195** (3.774)	0.485** (0.223)	803.745** (351.858)
Observations	765	765	765	765
Dep. var. mean	0.754	8.767	0.040	87.908
Indep. var. mean	0.035	0.035	0.035	0.035
KP F-statistic	18.82	18.82	18.82	18.82

Notes: The observations are at the State Economic Area (SEA)-year level. The dependent variables are: an indicator for whether the SEA has any labor union (column 1); the log of one plus the number of union branches (column 2); union density, defined as the number of union members divided by the total male nonfarm labor force (column 3); and the number of members per branch, or zero if the SEA has no union branch (column 4). The mean of the dependent variable in column (2) reflects the average number of union branches, not the log-transformed value. The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the SEA. The instrument used to predict it is described in Section 4.2. All regressions include SEA and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the SEA. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by SEA, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table B.12: Omitting or Controlling for Interpolated Observations

		Dependent variable:		
	Any Union Present (1)	Number of Union Branches (2)	Union Density (Members / LF) (3)	Union Members per Branch (4)
<i>Panel A: Omit observations with interpolated union data</i>				
Share of Immigrants	2.874** (1.285)	4.192** (1.701)	0.371*** (0.119)	553.255*** (180.087)
KP F-statistic	57.07	57.07	57.07	57.07
Observations	2,426	2,426	2,426	2,426
<i>Panel B: Control for whether observation has interpolated union data</i>				
Share of Immigrants	2.052* (1.149)	3.010** (1.504)	0.232** (0.106)	442.368*** (156.520)
KP F-statistic	65.77	65.77	65.77	65.77
Observations	2,628	2,628	2,628	2,628

Notes: The observations are at the county-year level. In Panel A, the observations where the union data are interpolated (as described in Section 3.1) are excluded from the sample; in Panel B, the sample is the same as in Table 3 and an indicator for whether the observation is interpolated is added among the controls. The dependent variables are: an indicator for whether the county has any labor union (column 1); the log of one plus the number of union branches (column 2); union density, defined as the number of union members divided by the total male nonfarm labor force (column 3); and the number of members per branch, or zero if the county has no union branch (column 4). The mean of the dependent variable in column (2) reflects the average number of union branches, not the log-transformed value. The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table B.13: Using Data Only From the State Convention Proceedings of the AFL

		<i>Dependent variable:</i>		
	Any Union Present (1)	Number of Union Branches (2)	Union Density (Members / LF) (3)	Union Members per Branch (4)
Share of Immigrants	2.221* (1.196)	4.033** (1.809)	0.182** (0.072)	416.133** (170.581)
Observations	2,628	2,628	2,628	2,628
Dep. var. mean	0.274	0.425	0.014	28.617
Indep. var. mean	0.028	0.028	0.028	0.028
KP F-statistic	65.27	65.27	65.27	65.27

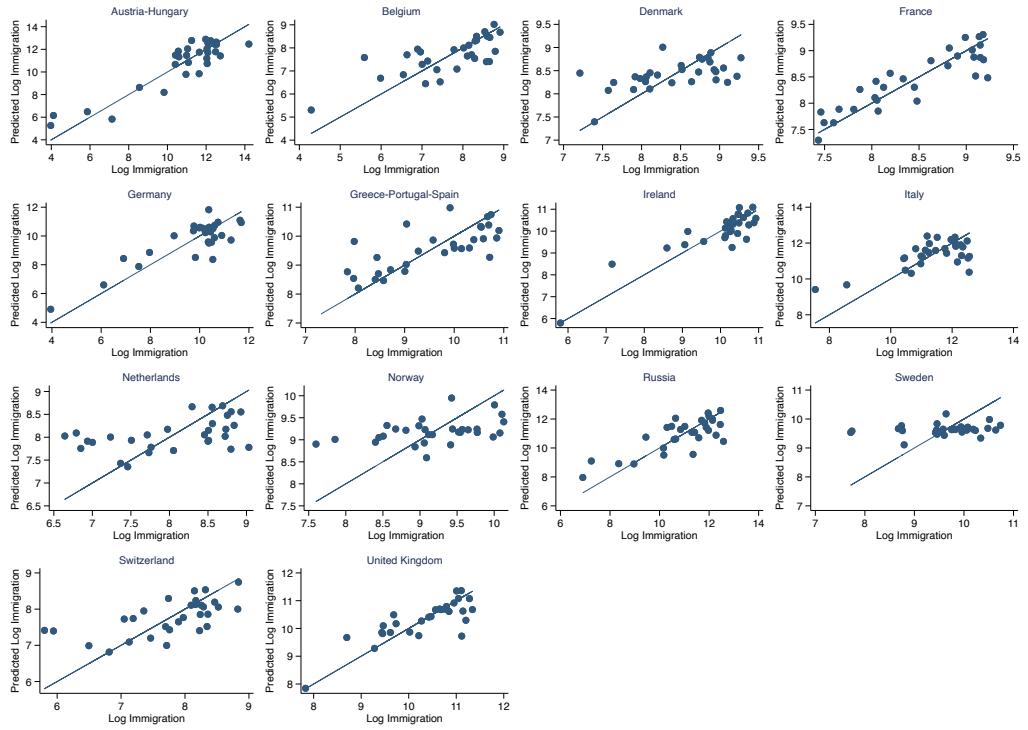

Notes: The observations are at the county-year level. The dependent variables are: an indicator for whether the county has any labor union (column 1); the log of one plus the number of union branches (column 2); union density, defined as the number of union members divided by the total male nonfarm labor force (column 3); and the number of members per branch, or zero if the county has no union branch (column 4). The mean of the dependent variable in column (2) reflects the average number of union branches, not the log-transformed value. The dependent variables are constructed using data from the convention proceedings of the state federations of labor (the state-level subordinate bodies of the AFL) only, without combining them with the convention proceedings of the AFL-affiliated national unions as in the rest of the paper (see Section 3.1 for details on the data sources and construction). The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county. The instrument used to predict it is described in Section 4.2. All regressions include county and year fixed effects, and the following controls, measured in 1890 and interacted with year dummies: the share of families in farming, the share of population in manufacturing, the number of coal mines per 1,000 people, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Standard errors, robust and clustered by county, are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Table B.14: Test of Pre-Trends in Unionization and Economic Outcomes

		<i>Dependent variable (1880–1890 difference):</i>			
	Any Union Present (1)	Share of Urban Pop. (2)	Nr. of Mfg. Establishments (3)	Total Mfg. Output (4)	Mfg. Output per Worker (5)
Share of Immigrants (average 1900–1920)	-1.077 (0.890)	-0.064 (0.314)	1.258 (1.547)	-0.190 (2.753)	-1.930 (1.222)
Observations	871	871	871	871	871
KP F-statistic	120.29	120.29	120.29	120.29	120.29

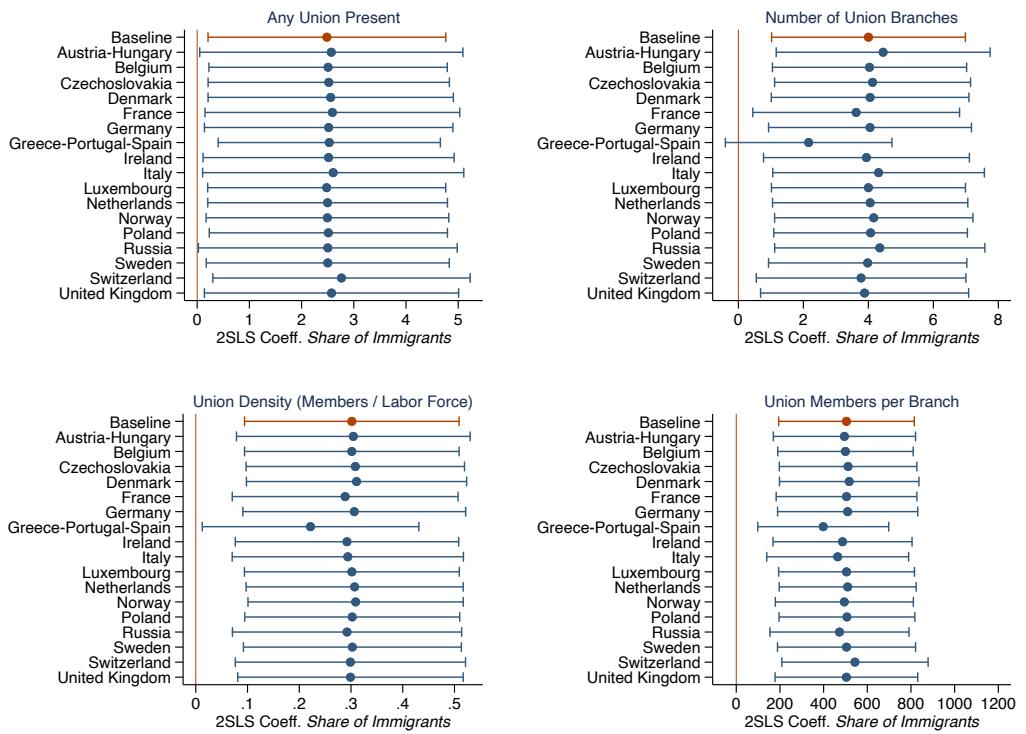

Notes: The observations are at the county level. The dependent variables are the 1890–1880 difference in: the presence of any branch of the Knights of Labor (column 1); the share of urban population (column 2); the log of one plus the number of manufacturing establishments (column 3); the log of one plus the value of manufacturing output (column 4); and the log of one plus the value of manufacturing output divided by the number of manufacturing workers (column 5). The regressor of interest is the number of European immigrants (men ages 16–64) who entered the United States in the previous decade, as a fraction of the male working-age population in the county, averaged over the period 1900–1920, and predicted by the instrument described in Section 4.2. All regressions include the following controls, measured in 1880: the share of population in farming, the share of population in manufacturing, the share of population in mining, and an indicator for the presence of a railroad in the county. KP F-statistic refers to the Kleibergen-Paap F-statistic for weak instruments. Robust standard errors are shown in parentheses. *** p<0.01; ** p<0.05; * p<0.1.

Figure B.1: Actual Versus Predicted Immigration Using Temperature Shocks

Notes: The figure displays the correlation between the actual (log) immigrant flows and those predicted using temperature shocks from equation (B.1), separately for each country (or group of countries) used to construct the shift-share instrumental variable.

Figure B.2: 2SLS Coefficients, Controlling for Initial Country Shares

Notes: The figures plot the 2SLS coefficients (with corresponding 95% confidence intervals) of *Share of Immigrants*, augmenting the preferred specification reported in Table 3 with the 1890 immigrant share from each sending country (relative to all immigrants from that country in the United States in that year), separately. The first coefficient at the top of each figure (in orange) corresponds to that from the baseline specification. Standard errors are robust and clustered by county.

C Mapping Delegates' Last Names to Origins and Ancestry

In Section 6, I use union delegates' last names to infer their ethnic origins. In this section, I describe how this mapping is constructed.

I start with de-anonymized full count U.S. Census data between 1900 and 1920, which contain information on names and birthplaces of the whole U.S. population. I then restrict the sample to the male population, and classify individuals depending on their country of birth and their ancestry, defined as their country of birth if born abroad, or the country of birth of the father if born in the United States from foreign-born father.

Then, I construct two probabilistic mappings: one between the last names and the country of birth, and one between the names and the ancestry. I compute $p_{l,e,t}$, the probability that a person with last name l is of country of birth (ancestry) e in year t , as $w_{l,e,t} = \frac{n_{l,e,t}}{N_{l,t}}$, where $n_{l,e,t}$ is the number of individuals with last name l from country of birth (ancestry) e in year t , and $N_{l,t}$ is the total number of individuals with last name l in year t . Based on this mapping, for example, the last name Smith in 1900 – the most common last name in that year – is 82% U.S.-born, 5% British, and 5% German (33% Germany ancestry, 31% British ancestry, and 22% Irish ancestry); Anderson – the eighth most last common name – is 46% U.S.-born, 32% Swedish, and 9% Norwegian (60% Swedish ancestry, 18% Norwegian ancestry, and 9% Danish ancestry); and Murphy is 47% Irish, 45% U.S.-born, and 2% British (94% Irish ancestry and 5% British ancestry).

Finally, after standardizing the names (e.g., remove spaces, hyphens, etc.), I match these probabilities to the delegates' last names from the digitized data. After collapsing the data at the county level, I obtain the expected number of delegates of country of birth (ancestry) e in county c and year t , which I then use to construct the shares of delegates from each country of birth (ancestry) that I employ in the analysis.

D Index of Residential Segregation

In Section 6, I explore the heterogeneity of the effects of European immigration on unionization with respect to the level of residential segregation in the county in 1880. In this section, I briefly describe how the measure is constructed.⁶¹

First, I identify next-door neighbors from full-count U.S. Census data as household heads with consecutive household serial numbers within the same enumeration district.⁶² Then, I follow the procedure described in [Logan and Parman \(2017\)](#), and I construct an indicator variable equal to one if a European immigrant has a next-door neighbor who is U.S.-born (from both U.S.-born parents).⁶³ The sum of this indicator variable across all European households in the county gives the number of European households with a U.S.-born next-door neighbor, x_c .

This number is first compared to the expected number that one would see under complete integration, $E(\bar{x}_c)$, i.e., a situation in which individuals were randomly assigned within neighborhoods by ethnic group. Then, x_c is compared to the number of immigrants with U.S.-born neighbors that one would observe under complete segregation, $E(\underline{x}_c)$, i.e., a situation where the immigrants living next to a U.S.-born would be only the individuals on either end of the immigrant neighborhood.

The index of residential segregation in county c , η_c , is computed as:

$$\eta_c = \frac{E(\bar{x}_c) - x_c}{E(\bar{x}_c) - E(\underline{x}_c)}. \quad (\text{D.1})$$

This segregation measure increases as European residents are more segregated within a county. The measure equals zero in the case of random assignment of neighbors (no segregation), and equals one in the case of complete segregation.

⁶¹For a more detailed discussion, I refer the reader to [Logan and Parman \(2017\)](#).

⁶²Restricting the definition of neighbors to household heads within the same Census page yields similar results (available upon request).

⁶³The original measure in [Logan and Parman \(2017\)](#) is constructed to compute an index of residential segregation for Black households. In the sample, instead of Black and white, the groups will be: foreign-born Europeans, U.S.-born from U.S.-born parents, and others.

E Labor Unions in Europe

The data on the presence and membership of labor unions in European countries used in Section 6.3 come from [Crouch \(1993\)](#). Estimates on union membership at the country level are available approximately every twenty or thirty years, starting in 1870. In most countries, the right to organize had been gained between 1860 and 1870, and was still often precarious. Similarly to the United States, organization was mostly prevalent among skilled craftsmen and mining workers. At the turn of the 20th century, the only countries with an active and strong labor movement were the U.K. and Ireland. By 1900, there had been some, but limited, union activity also in Austria, Belgium, Denmark, France, Germany, Italy, the Netherlands, Norway, Sweden, and Switzerland, although most of it had started only in the year 1900 or after ([Crouch, 1993](#)).

In Section 6.3, I separately predict (and estimate the impact of) immigration from the U.K. and Ireland (i.e., those with an active labor movement), and all the other European countries in the sample. The logic behind this exercise reflects the fact that individuals emigrating from countries with stronger unions may have been exposed to the experience of collective bargaining by the time they arrived to the United States, and therefore might have been particularly interested in forming or joining labor unions in their new country. Table E.1 reports union membership at the national level for the years 1870 and 1900.

Table E.1: Union Membership Across European Countries, 1870 and 1900

Country	Members (as % of LF)	
	1870	1900
Austria	0.28	1.00
Belgium	2.42	3.29
Denmark	0.54	8.76
France	0.20	2.99
Germany	0.39	3.40
Italy	n.a.	3.07
Norway	n.a.	2.30
Sweden	n.a.	2.53
U.K. and Ireland	8.32	12.50

Notes: This table presents estimates of union membership in European countries for the years 1870 and 1900. Data are from [Crouch \(1993\)](#).

F Support for Socialist Parties in Europe

In Section 6.3, I separately predict (and estimate the impact of) immigration from European countries with high and low support for socialism, using data from [Austrian National Library \(2024\)](#), [Mackie and Rose \(2016\)](#), and [Nohlen and Stöver \(2010\)](#). The logic behind this exercise reflects the fact that individuals emigrating from countries with stronger socialist parties may have been exposed to the ideas of socialism by the time they arrived to the United States, and therefore might have been particularly interested in continuing that experience in their new country by forming or joining labor unions.

Table F.1 reports the vote shares for socialist parties in national elections held in European countries between 1890 and 1919. In Table A.11, I classify European countries as having high support for socialism if they have an average vote share for socialist parties between 1890 and 1919 above 20% (Panel A) or above 10% (Panel B). Both definitions include the following countries as showing high support for socialism: Austria-Hungary, Denmark, Finland, and Germany; the latter classification also includes: Belgium, France, Italy, Luxembourg, Norway, Sweden, and Switzerland. In addition, the countries part of the Russian Empire are classified as having high support for socialist parties according to either definition.⁶⁴

⁶⁴The results (not shown for brevity, but available upon request), are very similar if such countries are classified as having low support for socialist parties instead.

Table F.1: Socialist Parties Vote Shares in National Elections Across European Countries, 1890–1919

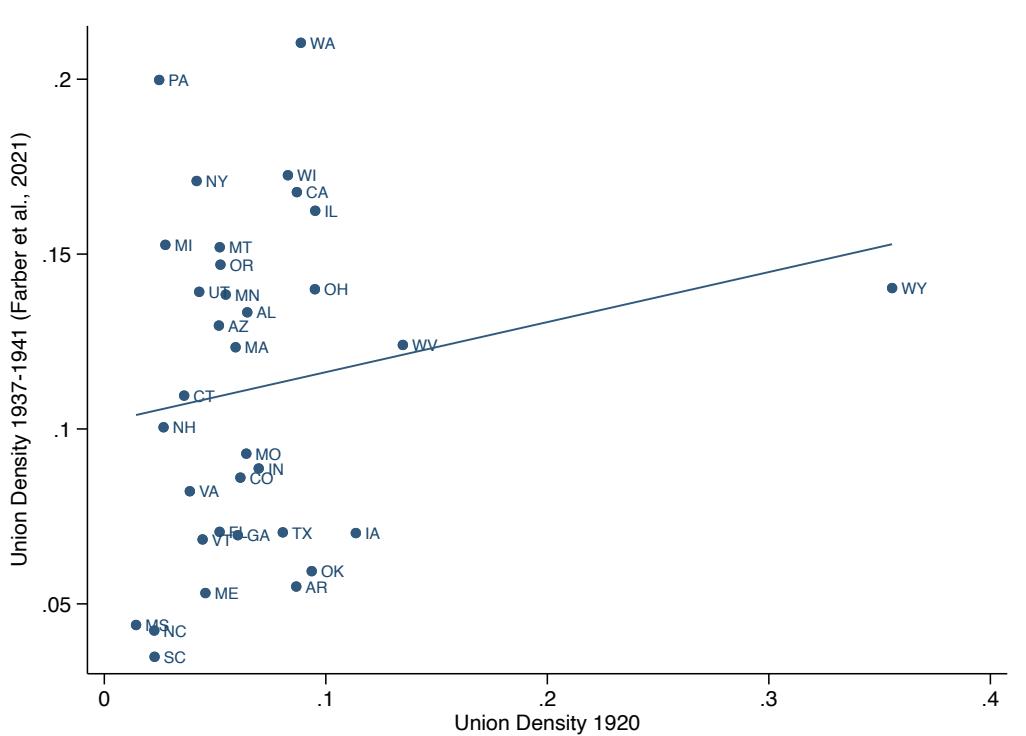

Year	Austria	Belgium	Bulgaria	Denmark	Finland	France	Germany	Iceland	Italy	Luxembourg	Netherlands	Norway	Poland	Sweden	Switzerland	U.K.
1890	0.30															19.70
1891		0.20														1.00
1892			0.20													
1893				8.40		23.30										0.20
1894					13.20											0.30
1895						6.80										1.00
1896							8.50									6.80
1897								23.13								
1898									11.30	21.60						9.60
1899										8.90						1.30
1900											3.50					
1901												11.30				
1902													17.10

1919	40.42	36.60	31.60													
																15.60
																22.00
																31.60
																22.50
																23.40

Notes: This table presents the vote shares obtained by socialist parties in national elections held in European countries between 1890 and 1919. The data are from Austrian National Library (2024), Mackie and Rose (2016), and Nohlen and Stöver (2010). The following parties are included in the count of the socialist vote shares. Austria: Social Democrats (SPD); Belgium: Workers' Party (BWP/POB); Bulgaria: Social Democratic Workers Party; Denmark: Social Democrats; Finland: Social Democrats; France: Socialist Party (SFIO); Germany: Social Democratic Party (SPD); Iceland: Social Democratic Party; Italy: Socialist Party (PSI); Luxembourg: Social Democratic Party (POS/L/LSAP); Netherlands: Social Democratic League (SDB) and Social Democratic Workers' Party (SDAP); Norway: Labor Party (DNA); Poland: Social Democrats; Sweden: Social Democratic Workers' Party (SAP); Switzerland: Social Democrats (PS/SP); United Kingdom: Independent Labour Party (ILP) and Labour Party.

G Validation of Unionization Data

In addition to the steps illustrated in Section 3.1 to ensure the accuracy and completeness of the data collected, in this Section I provide a validation of the estimates of union density. In particular, I explore their correlation with the only other measures available in a historical period. Such data come from Farber et al. (2021), who harmonize household-level survey data from Gallup starting in 1937. In Figure G.1, I show a scatter plot between the two measures, where the data from this paper are aggregated at the state level to match the unit of observation from Farber et al. (2021). Unfortunately, the two sources do not overlap in time. Therefore, the figure plots on the x-axis the union density from this paper in 1920 and on the y-axis the measure of union density from Farber et al. (2021), calculated as an average of the first five years of observations (1937–1941). Although the two measures do not agree in levels (and they are not expected to, since by 1937 several new industrial unions had been constituted, which represented large masses of workers previously unorganized), they display a positive correlation (which becomes stronger once Wyoming, an outlier in the figure, is excluded from the sample).

Figure G.1: Correlation Between Data of This Paper and State-Level Gallup Data

Notes: The figure plots a scatter plot for state-level union density measured in 1920 using the newly collected archival data (x-axis) and average union density between 1937–1941 measured using Gallup data as in Farber et al. (2021). See Section 3 for more details on the dataset on labor unions I assemble for the period 1900–1920.
